4314. The common *draining auger* (fig. 862) consists of four parts, the shell or wimble, the chisel, the rod, and the handle. The auger shell, or wimble (e) as it is variously called, for excavating the earth or strata through which it passes, is generally from two and a half to three and a half inches in diameter: the hollow part of it one foot four inches in length and constructed nearly in the shape of the wimble used by carpenters, only the sides of the shell come closer to one another. The rods (a) are made in separate pieces of four feet long each that screw into each other to any assignable length, one after another as the depth of the hole requires. The size above the auger is about an inch square, unless at the joints, where, for the sake of strength, they are a quarter of an inch more. There is also a chisel and punch (b), adapted for screwing on in going through hard gravel, or other stony substances, to accelerate the passage of the auger which could not otherwise perforate such bodies. The punch is often used, when the auger is not applied, to prick or open the sand or gravel, and give a more easy issue to the water. The chisel is an inch and a half or two inches broad at the point, and made very sharp for cutting stone; and the punch an inch square, like the other part of the rods, with the point sharpened also. There is a shifting handle of wood (d), fastened by means of two iron wedges affixed to it for the purpose of turning round the rods in boring; and also two iron keys (f & c) for screwing and unscrewing the rods, and for assisting the handle when the soil is very stiff, and more than two men required to turn it.

4315. To judge when to make use of the *borer* is a difficult part of the business of draining. Some have been led into a mistaken notion, both as to the manner of using it and the purpose for which it is applied. They think they do, by boring indiscriminately through the ground to be drained, water is found near enough the surface to be reached by the depth of the drain: the proper direction for it is along these holes where water has been found: and thus they make it the first implement to be used. The contrary is the case, and the auger should never be used till after the drain is cut: and then for the purpose of perforating any retentive or impervious stratum, lying between the bottom of the drain and the reservoir or strata containing the spring. Thus does it greatly lessen the trouble and expense that would otherwise be requisite in cutting the trench to a depth which in many instances, the level of the outlet will not admit.

4316. The manner of using it is simply thus:—In working it, two, or rather three men are necessary. Two, standing above, one on each side of the drain, turn the auger round by means of the wooden handles, and when it is full they draw it out, and the man in the bottom of the trench clears out the earth: again in pulling it out, and drawing it into the hole, and he can also assist in turning with the iron handle or key when the depth and length of rods require additional force to perform the operation. The workmen should be cautious, in boring, not to go deeper at a time, without drawing, than the exact length of the shell: otherwise the earth, clay, or sand through which it is boring after the shell is full makes it very difficult to pull out. For this purpose the exact length of the shell should be regularly marked on the rods, from the bottom upwards. Two flat boards, with a hole cut into the side of one of them, and held side by side across the drain, are very useful in directing the rods perpendicularly in going down, for keeping them steady in boring, and for the men to stand on when performing the operation.

4317. The *horizontal auger* (fig. 863) is another boring instrument employed in particular cases. It was invented by Holford, of Holford, in Leicestershire, but is little used. The advantages of it are, in some cases, considerable, by lessening the expense of cutting, and performing the work in a much shorter time. Where a drain or water-course has to pass under a bank, road, hedge, wall, rivulet of water, or the

dipping mast-pole, &c. it may be used to advantage in excavating a sufficient passage for the water without opening a trench. In laying leaden pipes for the conveyance of water it is also useful in making a hole

in which the pipe may be laid, without opening a cut on purpose. For tapping springs, or finding water at the bottom of a well, either for the supply of a house, or for draining the ground, it may likewise be used with success as the water of the spring when hit on, will flow more easily and in greater abundance through a horizontal or level, than through a perpendicular outlet.

4318. *The manner of using it is this* — Suppose a lake or pond of water surrounded with high banks to be emptied if the ground declines lower on the opposite side find the level of the bank where the perforation is to be made. Then smooth the surface of the ground so as to place the frame nearly level with the auger, pointing a little upwards. It requires two men to turn the handles at top (a), in order to work it — and when the auger or shell is full, the rods are drawn back by reversing the lower handle (b). Other rods are added at the joint when the distance requires them. In boring through a bank of the hardest clay, two men will work through from thirty to forty feet in a day provided there is no interruption from hard stones, which will require the chisel to be fixed on in place of the shell, and longer time to work through. If the length to be bored through is considerable, or longer than the whole length of the rods, a pit must be sunk upon the line, down to the hole, for placing the frame when removed, and the operation carried on as before.

## CHAP. II

*Embanking and otherwise protecting Lands from the Overflowing or Encroachment of Rivers or the Sea.*

4319 *Lands adjoining rivers or the sea are frequently liable to be overflowed or washed away, or to be injured by the courses of rivers being changed during great floods. These evils are guarded against by embankments and piers or by these constructions joined to deepening or straightening the courses of rivers, and we shall therefore treat in succession of embankments and of improving the courses of rivers.*

### SECT. I *Embanking Lands from Rivers or the Sea.*

4320 *The great value of alluvial soil to the agriculturist no doubt gave rise to the invention of banks, or other barriers, to protect soils from the overflowing of their accompanying rivers. The civilized nations of the highest antiquity were chiefly inhabitants of valleys and alluvial plains the soil, moisture, and warmth of which, by enlarging the component parts and ameliorating the fruits of the vegetable kingdom, afforded to man better nourishment at less labour than could be obtained in hilly districts. The country of Paradise and around Babylon was flat, and the soil saponaceous clay occasionally overflowed by the Euphrates. The inhabited part of Egypt was also entirely of this description. Historians inform us that embankments were first used by the Babylonians and Egyptians, very little by the Greeks, and a good deal by the Romans, who embanked the Tiber near Rome, and the Po for many stadia from its embouchure. The latter is perhaps one of the most singular cases of embankment in the world.*

4321 *The oldest embankment in England is that of Romney Marsh as to the origin of which, Dugdale remarks, "there is no testimony left to us from any record or historian." (History of Embanking and Draining) It is conjectured to have been the work of the Romans, as well as the banks on each side of the Thames, for several miles above London, which protect from floods and spring tides several thousand acres of the richest garden ground in the neighbourhood of the metropolis. The commencement of modern embankments in England took place about the middle of the seventeenth century, under Cromwell. In the space of a few years previous to 1651, 425,000 acres of fens, marshes, or overflowed muddy lands, were recovered in Lincolnshire, Cambridgeshire, Hampshire, and Kent and let at from 2s. 6d. to 50s. an acre. (Hart's Essay, p. 54. 2d edit.) Vermuyden a Fleming by birth, and a colonel of horse under Cromwell, who had served in Germany during the thirty years' war was the principal undertaker of these works. Some farther details of the history of embanking will be found in the*

*Reporters of Patents Inventions*, for January, 1826, and in the *Bulletin des Sciences Agricoles*, for November, 1827.

4392. *Very little has been written on the subject of embankments*, as a separate branch of art, by British authors. Dugdale's work is entirely historical and topographical. But the writings of Smetton, Young, Gregory &c. contain the general principles on which is founded the art of embanking, and every other operation connected with water, and Bentham, in *Communication to Board of Agriculture*, Dr Anderson, Marshal, and some others, have written on the practice of the art. The works of this sort constructed in our own times will be found described in the *Agricultural Reports* of the maritime counties, especially of Lincolnshire, by Arthur Young. We shall first submit some general remarks on the principles of designing embankments, and next describe the principal kinds of banks, with their application.

#### SUBJECT 1 General Principles of designing Embankments.

4393. *The theory of embanking*, Marshal observes, is beautifully simple. The outward waters having been resisted by a line of embankment, and having receded those that have collected internally are enabled, by their own weight, to open a valve placed in the foot of the bank, and effect their escape thus securing the embanked lands from inundation, though beset on every side with water.

4394. *The pressure of still water against the sides of the vessel containing it being as its depth*, it follows, that a bank of any material whatever impervious to water, whose section is a right-angled triangle, and the height of whose perpendicular side is equal to that of the water it is to dam in, will balance or resist this water whatever may be the breadth of the surface of the latter and therefore that, as far as width or extent is concerned, it is just as easy to exclude the Atlantic Ocean as a pond or a river of a few yards in width.

4395. *Embankments may be considered in regard to their situation, direction, construction, and materials.*

4396. *The situation of the bank should be such that its base may not be unnecessarily exposed to the immediate action of the waves or the current* and where the quantity of water is limited, as in the case of land-floods in a particular river the more room it has to spread, the less height and strength the bank will require and the power of the current will be proportionably lessened. It is to be recollected, however in all cases where the channel of the water is liable to be warped or filled up by siltage, that the narrower the space is, in which the water is confined, the stronger will be its current, and the less silt will, in ordinary cases, be deposited.

4397. *The direction of embankment should be free from sharp angles*, so as to occasion the least possible resistance to the current, whether of a land-flood or the tide.

4398. *In the construction or form of the bank there are certain principles to be observed*. Its height and strength ought ever to be proportioned to the depth and the pressure of water which it will have to sustain and, to increase its firmness, the inner face should lean towards it, as a buttress. But it is on the construction of the outer face its strength, firmness, and durability principally depend. This ought to be made sloping, to a degree of fatness, for the twofold purpose of preventing resistance and taking off the weight of water in difficult cases, the outer surface may form an angle with a perpendicular line of 45 to 60 degrees, according to the force to be guarded against, and the materials to be employed.

4399. *The materials of the body of the bank* as well as of the inner face! where the foundation is sound and firm and the bank can be carried up at a proper season, without great molestation from the water, may generally be the natural soil of the lands to be embanked and, where merely the weight of stagnant or slowly moving water is to be guarded against, the outer slope may be of the same material. But where force, whether of waves or a strong current, will act immediately upon the bank, its outer face ought to be made proof against it and its base should be particularly guarded, to prevent its being undermined the most mischievous and irreparable disaster of embankments. Hence, when the foundation is not sufficiently firm, piles, timber and masonry may be required, to ensure success, and no man ought to begin a work of this nature without attentively guarding it against every probability of miscarriage.

4400. *A system of drains and floodgates is requisite for the purpose of freeing the embanked lands from internal waters.*

4401. *In designing and setting out the main drain, or discharging channel* on the outside of the embankment, these are points which require particular attention. The situation of the outlet, or mouth with respect to the current of the water into which it opens, is of considerable importance. It ought to be such that the current of the water received will not warp up the channel of the drain but such on the contrary as will tend to clear the mouth and keep the channel free. If it were not to preserve the requisite character of an elementary work, it might be deemed unnecessary to add, that the mouth of the discharging drain should be situated as low beneath the floodgate of the embankment as given circumstances and a prudent expenditure will allow, in order that, by inducing a sufficient current, the floodgate, as well as the mouth of the channel, may become free from obstruction. Against the open sea, or a wide estuary where there is no discharging channel, but where the waves reach the foot of the embankment, two floodgates may be required, one on the outer side, to sustain the force of the waves, and prevent their blowing up the inner works; the other within, to secure the passage the more effectually. The outer gate in this case is liable to be hindered with the agitation of the waves, and thereby to admit much water but the inner valve, being in an undisturbed situation, effectually stops its progress.

4402. *Where the discharge is made directly behind a drying beach*, and especially where the floodgate is necessarily placed level with or beneath the general surface of the gravel but is, through which the waters have been wont to force a channel, the valve is liable to be buried and the channel to be closed up by every spring tide, and by every gale of wind which acts in upon it and cannot be kept free but by increasing labour and expense. In an obnoxious case of this kind on Lord Cawdor's estate, in Pembrokeshire, the discharging floodgate is defended by a covered channel, carried out through the line or ridge of beach into the sea being made strong enough to sustain the weight of the heaviest breakers. This, it is true, has been effected at a great expense, but nevertheless, the improvement being of considerable magnitude with great profit. In every case where an external valve is required, and where it is liable to be raised up, or loaded with sand or gravel, great attention to the outward channel is necessary or some defence must be constructed; for the floodgate, when loaded, cuts off all communication between the point up water and the materials that impound them. They cannot, by loosening the obstructing matter as

waters would otherwise direct them, force their way through it; nor by surmounting it, can they wear down a channel, and thus set themselves at liberty.

4393. In ordinary cases, the outer floodgate may be guarded by a pile fence or jetty, run out from the foot of the embankment, across the known drift of the beach; and in such a manner as not to interrupt the outfall channel of the water; the gravel &c. which such a safeguard may accumulate being removed from time to time at occasions they require.

4394. The best construction of the flood-gate for the uses now under consideration is the common valve hinging at the top swinging outward and falling into a rabbeted frame. In forming and hanging a floodgate of this construction, there are a few particulars worthy of attention. It should be made of seasoned wood and ought to be double; the boards or planks of which it is formed being made to cross each other to prevent its swelling. It should fall truly and fit neatly within a surrounding rabbet (so lessen the power of the waves to lift it), but not so closely or tight as to stick when swelled by moisture. To prevent this, as well as to give it additional tightness, its edges should not be square, but should bevel somewhat inward in the manner of a bung; the rabbet in the frame being made to answer it. In fixing the frame, it ought to be suffered to lean or batter inward; in which position the door will shut closer and be less liable to the action of the waves in an exposed situation than it would if it were hung perpendicularly. It ought not, however, to be so flat or heavy as to prevent the free escape of the internal water. The floodgates or self-acting sluices at Bar Loch embankment fall against a flat surface (fig 664). A writer in the *Perth Miscellany states*, (vol. i. p. 41) that many of the tunnels in the embankments of the Tay have only wooden valves with iron hinges, and a lid of lead or iron nailed on for weight to keep them down. These he says, are not to be depended on, and he has accordingly had some tunnels made of two inch plank with the end cut at an angle of  $45^\circ$  for the valve, and placed on a slope of 8 inches in 12 feet, the water being discharged on a broad piece of pavement. He had an iron plate "fast the exact use of the mouth of the tunnel, and about half an inch thick, with holes drilled in 6 inches apart, and three-fourths from the edge of the plate, for riveting a piece of saddle's leather

or shoemaker's brown sole, which extended at least two inches beyond the plate, and covered the whole end of the tunnel, the upper end of the leather nailed to the wood serving as hinges and the edges of the mouth previously lined with the same material. Thus the strength of the tide never raises the valves, and completely prevents the water from getting in." (p. 42.)

4395. The internal waters which rise with a or fall upon the area of the embanked lands, are to be collected by a main drain, continued upward from the floodgate, and furnished with branches to spread over every part of the field of improvement, so as to draw the water from every dip and hollow place as it collects, and thus free the surface effectually from stagnant water saving such only as may be wanted for the use of pasturing stock.

4396. If alien waters have a natural and accustomed channel through the embanked area, it may be found necessary to raise a suitable bank at a proper distance on each side of the stream in order to prevent its overflowing the area in time of floods. Where it is found that an outlet cannot be had low enough to free the area entirely from surface water it is requisite (though no alien waters intrude) to form an embanked channel or reservoir to gain the required outfall, and to throw the waters which lodge on the lower grounds into this receptacle, by a drawing mill, of which there are a great variety of constructions.

4397. An embanked channel if the banks are raised high enough, or are placed wide enough asunder so as to contain a sufficient body of water may have a further use, which, in some cases, may be of the highest importance to an improvement of this nature. For by the help of folding floodgates, such as are commonly seen in use for the locks of navigable canals, placed at the lower end of this canal or reservoir a body of water may be collected and rapidly discharged by which easy means, not only the channel of the outer drain, but its mouth, if judiciously contracted, may from time to time be cleared from obstructions. Where alien waters of a good quality pass through the field of improvement, an embanked channel may be profitably applied in watering the lands and where alien waters, which have not a natural or fortuitous passage through it can be commanded, and conducted to it at a moderate expense, they may prove highly beneficial for either or both of these purposes.

#### SUBJECT 2. Different Descriptions of Banks in general Use for excluding Waters.

4398. Mounds or banks for excluding rivers or the sea are generally formed of earth, but sometimes also of masonry and even of wood. Embankments of common earth are sufficient for resisting occasional floods. If this earth be loose, the bank will require to be spread out at the base, at the rate of one foot and a half or two feet horizontal for every foot in height that is to say a bank of loose earth three feet high will require to be nine feet or twelve feet broad. If the earth to be made use of is a compact clay, or if turf of a solid and compact body can be procured, the slope of the bank may be much steeper according to its height and the depth of water which may be expected to press against it.

4399. The earthen wall (fig 665.) is the simplest description of embankment, and is frequently erected by temporary occupiers of lands on the general principle of enclosing and subdividing, which is sometimes made a condition of tenure between the landlord and tenant. This wall applies to lands occasionally, but rarely overflowed or inundated and is set out in a direction generally parallel to the river or shore. Its base is commenced on the surface from two to five feet wide, regularly built of turf on the outside, with the grassy sides underneath. The middle of the wall is filled up with loose earth. The wall is carried up with the sides bevelled towards the

centre, so as to finish in a width of one foot or eighteen inches, at five or six feet in height. Collaterally with such walls, and at the distance of three or four feet, a small open drain is formed, as well to collect the surface water of the grounds within, as that which in time of floods will necessarily ooze through a wall of this construction. The water so collected is let through the wall by tubes, or tunnels of boards, with a valve opening outwards on their exterior extremity. When the flow of water from without approaches, it shuts the valve, which remains in this state till the flood subsides, when, the height of the water within being greater than that without, it presses open the valve and escapes. Walls and valves of this kind are common enough in the drier parts of the fenny districts of Lincolnshire and Cambridgeshire.

4340. The earthen mound (fig 666) is the most general description of embankment, and as it is executed at considerable expense, is only undertaken by such

as have a permanent interest in the soil. This barrier applies to sea lands overflowed by every spring tide, and to alluvial plains inundated by every flood. It is set out in a direction parallel to the shore, and to the general turns of the river but not to its minute windings and it is placed farther from or nearer to the latter according to the quantity of water in time of floods, the rapidity of the current from the declivity of the bed, the straight course of the stream, and the intended height of the bank. The two sides of such a mound are generally formed in different slopes. That towards the land is always the most abrupt, but can never be secure if more so than  $45^\circ$  that towards the water varies from  $45^\circ$  to  $15^\circ$  the power of the bank to resist the weight of the water as well as to break its force when in motion, being inversely as its steepness. The power of water to lessen the gravity of bodies, or in other words, to loosen the surfaces over which they flow or stand, is also lessened in a ratio somewhat similar.

4341. The formation of the earthen mound consists merely in taking earth from the general surface of the ground to be protected, or from a collateral excavation distant at least the width of the mound from its base line, and heaping it up in the desired form. The surface is then in general cases covered with turf, well rolled in order to bind it to the loose earth. The earth of such mounds is generally wheeled in barrows but sometimes it is led in carts placed on a wooden roller instead of wheels which with the treading of the horses, serves in some degree to consolidate the bank.

4342. The *concection* serves the same purpose as the open drain in the earthen wall and similarly constructed sluices or valves are introduced on a larger scale. Sometimes, also, the interior water is drawn off by windmills, and thrown over the mound into the river. This is very common in Huntingdonshire, and might be greatly improved on by employing steam engines for entire districts, one of which, of a ten horse power would do the work of twenty mills, and thus in calm weather when the latter cannot move.

4343. Embankments of this description are the most universal of any and their sections vary from a scalene triangle of ten feet in base, and three feet in height, as on the Forth near Stirling, and the Thames at Fulham, to a base of 100 feet, and a height of ten feet, as in the great bank of the Ouse near Wisbeach. The great rivers of Germany and Holland are embanked in this way when so far from the sea as to be out of the reach of the tide, as the Vistula at Marienwerder the banks of which near Dantzig are above fifteen feet in height, the Oder the Elbe, &c. All these banks are closely covered in every part with a grassy surface, and sometimes ornamented with rows of trees.

4344. Near the sea, where such banks are washed by every tide when the course of the wind is towards the shore, and by all land floods and spring-tides, grass is only to be found on and near their summits. The rest of the bank is bare, and to preserve it from the action of waves, currents, and the stones, pieces of wood, and other foreign matters which they carry with them, the surface is covered with gravel, reeds, or straw kept down by pieces of wood. Aggots, wicker hurdles, nets of straw ropes, straw ropes laid side by side and fastened, or handfuls of straw fixed in the ground with a gibber (*Near's* Traps as Germany &c. chap. 1.) or any other contrivance, according to the situation, to prevent the wash ng away of the bank. It is common to attribute to these coverings the power of breaking the force of the waves; but this power depends, as we have already stated, on the slope of the bank and its smoothness, and the use of the surface covering, and of the constant attention required to remove all obstacles which may be left on it by floods and tides, is to prevent the loosening power of the water from wearing it into holes. For this purpose a sheet of canvas or straw-netting is as good, whilst it lasts, as a covering of plain iron or stone pavement.

4345. All banks whatever require to be constantly watched on time of floods or spring-tides, in order to remove every object, except sand or mud, which may be left by the water. Such objects, put in motion by the water in a short time wear out large holes. These holes, presenting abrupt points to the stream, act as obstructions, soon become much larger and if not immediately filled up, turned over and the turfs pinned down or the new turfs repaired by some other means not easily softened and raised up by the water will end in a breach of the bank. A similar effect is produced by a surface formed of unequal degrees of hardness and durability. The banks of this description in Holland, at Cuxhaven and along the coast of Lincolnshire, are regularly watched throughout the year, the surface protection is repaired whenever it goes out of repair as is the body of the bank in the summer season.

4346. The mound with puddle wall (fig 667) It generally happens that the earth of

such banks is alluvial, and their foundation of the same description but there are some

cases where the basis is sand, silt, or gravel or a mud or black earth, as in some parts of Cambridgeshire and Lincolnshire, which does not easily become so compact. Here it is common, before beginning the bank, to bring up from the solid substratum (a) what is called a puddle-ditch, or section of clay in the centre of the highest part of the mound in the direction of its length, and of three or five feet wide, according to the depth of the stratum of silt (b), and the intended height of the bank (c). When the clay of this puddle-ditch is well worked, either by men's feet or clay rammers, the bank will be perfectly impervious to water and if against a mild stream or shore, need not contain such an accumulation of earth as where the imperviousness of the bank to water depends chiefly on the mass of materials. As already observed, the important point to attend to in this variety of mound is, to found the section, or wall of clay so deeply as to be in contact with a stratum (a), either by induration, or its argillaceous nature, impervious to water. In the drainage of the Bar Loch in the county of Renfrew considerable difficulty was experienced in some places in getting to the bottom of the sandy subsoil, so as to bring up the

puddle wall from the retentive stratum. Such was the difficulty in some cases, that the puddle could not be carried up perpendicularly but a puddle wall being raised within the bank, as high as the natural surface, it was joined horizontally to another puddle wall in the body of the bank (fig 668)

4347. Puddling is often found defective, owing to the imperfect working of the materials. Many think that when clay is used, if it be worked into the consistence of dough, it is sufficient but this is a mistake it should be slaked and so decomposed by the labour of proper tools and treading and so completely saturated with water that the whole mass becomes one uniform and homogeneous body and almost fluid

4348. Mounds with reversed slopes. In some cases of embanking rivers, as where they pass through parks, it is desirable to conceal, as much as possible the appearance of a bank from the protected grounds. Hence the mound is simply reversed, the steepest side being placed next the water. It is proper to observe, that such banks are not so strong by the difference of the weight of the triangle of water which would rest on the prolonged slope, were it placed next the river and are more liable to be deranged in surface in proportion to the difference of the slopes, the water acting for a longer period on every part of the slope.

4349. Mound faced with stones. This is the same species of mound, with a slope next the water of forty five or fifty degrees, paved or causewayed with stones or timber. In Holland this pavement or causeway is often formed of planking or bricks but in England generally with stones, and the mortar used is either some cement which will set under water or what is better, plants of moss firmly rammed between them. The objections to such banks are their expense, and their liability to be undermined invisibly by the admission of the water through crevices, &c. They are, therefore, chiefly used where there is little room, or where it is desirable to narrow and deepen the course of a river

4350. The bank formed with piles, brushwood, and stones, is occasionally used for protecting moving sands, or directing the course of streams flowing through a sandy shore. A dike or bank for the latter purpose (fig 669) has been erected on the river Don in Aberdeenshire. It consists of piles or poles,

being the thinning of plantation of Scotch pine and larch, driven six feet into the sand (a a a) the spaces between these piles (b b) are filled in with furze or other spray or small branches and on the top of them, are wedged in stones to keep them down. On the side of this row of piles next the river stones (c) from 30 lbs. to half a ton weight each, are precipitated from a punt, until they form a bank of an angle of nearly 45°. On the outside of this bank and piles, the sand (d) gradually drifts up, and forms a bank, which, being planted with *Arundo arenaria* and other grasses, gradually becomes covered with verdure. (Highland Soc. Trans. vol. vii. p. 91)

4351. Mound protected by a wicker hedge. This is a Dutch practice and, where appearance is no object, has the advantage of not requiring watching. Wicker-work, however, subjected to the strain of waves, will be obviously less durable, than where it lies flat on the ground and can only decay chemically. This wicker hedge is sometimes a series of hurdles supported by posts and studs but generally in Britain it is a dead hedge or row of stakes, wattled or wrought with bushes presenting their spray to the sea or river. Besides placing such a hedge before a bank, others are sometimes placed in parallel rows on its surface, the object of which is to entrap sand, shells, and sea weeds, to increase the mass of mound, or to collect shells for the purpose of carrying away as manure

4352. The sea wall (Ag. 670.) is an embankment formed to protect abrupt and earthy shores or banks of rivers, and consists of a wall, varying in thickness, and in the inclination of its surface, according to the required height, and other circumstances. Behndor in his *Traité de Hydraulique*, has given the exact curve which the section of such a wall ought to have (a b), in order to resist loose earth, and which is somewhat greater than where the earth behind the wall is supposed to be chiefly firm. Some fine examples of such walls, for other purposes, occur in the

Caledonian Canal and perhaps the finest in the world are the granite walls which embank the Neva at Petersburg the construction of which may serve as an example of a river cased with stone on a foundation of soft bog earth.

4353. *Embankments for fixing drifting-sands, shells or mud.* In several tracts of coast, the sea at ordinary tides barely covers a surface of sand and these sands, in dry weather during high winds, are drifted and blown about in all directions. Great part of the north shores of the Solway Frith, of Lancaster Bay and of the coast of Norfolk is of this description. Young in his *Farmer's Letters*, informs us, that a considerable part of the county of Norfolk was drift sand, and even as far inland as Brandon in Suffolk, before the introduction of the turnip culture and Harte (*Essay I*) states that some of what is now the richest land in Holland, was, about the middle of the sixteenth century, of this description. The suggestion of any mode, therefore, by which, at a moderate expense, such tracts could be fixed, and covered with vegetation, must be deemed worthy of notice. The mode which nature herself employs is as follows. After the tides and wind have raised a marginal steep of land as high as high water mark, it becomes by degrees covered with vegetation, and chiefly by the *Elymus arenarius*, *Trifolium yuccifolium* various species of *Juncus*, and sometimes by the *Galium verum*. With the exception of the first of these plants (the leaves and stalks of which are manufactured into mats and ropes in Anglesea, and the grain of which is sometimes ground and used as meal in Ireland) they are of no other use than for fixing the sands, which, being composed in great part of the debris of shells, expand as they decay and contribute to raising the surface still higher when the fibrous roots of good grasses soon destroy the others. The *Arundo arenaria* is planted in Holland for the purpose of binding sands, and was extensively introduced into the Highlands of Scotland for the same purpose, by Macleod of Harris, in 1819. (*Trans. Highl. Soc. vol. vi. p. 265*)

4354. To assist nature in fixing drift-sands, it is only necessary to transplant the *Elymus*, which is to be had in abundance on almost every sandy coast in Britain; and as it would be liable to be blown away with the sands, if merely inserted in the common way it seems advisable to tie the plants to the upper ends of willow or elder rods, of two or three feet in length and to insert these in the sand, by which means there is the double chance of the grass growing, and the truncheons taking root. The elder will grow exposed to the sea breeze, and no plant throws out so many and such vigorous roots in proportion to its shoots.

4355. The mode by which such sands were fixed in Holland was by the formation of wicker-work embankments, and by staking in the sands branches of trees, bushes, furze, &c. in all directions. These obstructed the motion of the sands, and collected masses of sand, shells or mud, and sea-weeds around them, which were immediately planted with some description of creeping grass or what was more frequent, covered with a thin coating of clay or alluvial earth and sown with clover. Though the most certain and least expensive mode of gaining such lands is undoubtedly that of seconding the efforts of nature, by inserting truncheons and planting the *Elymus* in this way yet it may sometimes be desirable to make a grand effort to protect an extensive surface by forming a bank of branches, which might, in a single or several tides, be filled with sand and shells. It is evident, that such a bank might be constructed in various ways but that which would be most certain of remaining firm, and effecting the purpose, would be one regularly constructed of framed timber the section of which would resemble a trussed roof each truss being joined in the direction of the bank by rafters, and the whole inside and surface stuck full of branches. To retain it firm, piles would require to be driven into the sand, to the upper parts of which would be attached the trusses. The height of such a barrier would require to be several feet above that of the highest spring-tides; and the more its width at base exceeded the proportion of that of an equilateral triangle the better.

4356. A mode suited to a less extensive scale of operation, is to intersect a sandy shore in all directions, with common dead or wicker work hedges, formed by first driving a row of stakes six or eight feet into the ground, leaving their tops three or four feet above it, and then weaving among these stakes, branches of trees, or the tops of hedges. The Dutch are said to weave straw ropes in this way and thereby to collect mud in the manner of sweeping. This mode, being little expensive, seems to deserve a trial in favourable situations; and in so doing, it must not be forgotten that much depends on the immediate management of the surface, after it is in some degree fixed. In an extensive trial of this sort at present in progress on the west coast of Scotland, under an English gentleman seeds and roots are baked in a mixture of loam, dung, and gravel, and then formed into masses, and scattered over a sandy surface. These, from their weight, will not, it is thought be moved by the water or the wind but, becoming more or less covered with sand, the mass will be kept moist, and the seeds and roots will grow and, fixing themselves in the soil, will in time cover the surface with verdure. The experiment is ingenious, and we hope will be crowned with success.

4357. *Embankments of cast iron* have been proposed to be constructed by Deebie, a civil engineer of London. He proposes to combine a series of caissons, made of cast iron, in ranges, agreeable to the required form of the intended embankment. The caissons are to be fastened together by dovetails, and, being hollow, are, when fixed in their intended situations, to be filled with stones and other materials, making them up solid. (*Newton's Journal*, vol. ii. p. 202)

## Part II. *Guarding the Banks and otherwise improving the Courses of Rivers and Streams.*

4358. The subject of *guarding the banks of rivers* is of considerable interest to the proprietors of lands situated in hilly districts where in the valleys and on the hill sides, the streams often produce ravages on the banks, and sometimes change their course.

4359. The natural *licence of rivers* Marshal observes, is not only destructive of landed property frequently of lands of the first quality but is often the cause of disputes, and not unfrequently of legal contentions, between neighbouring proprietors. A river is the most unfortunate boundary line of an estate. Even as a fence, unless where the water is unfordable, a river or rapid brook which is liable to high floods, is the most tormenting and inefficient. Proprietors have therefore a double interest in accommodating each other, as circumstances may require, with the lands of river banks, so as to be able to fix permanent boundary lines between their properties. When the owners of estates cannot, by reason of entails or settlements, or will not for less cogent reasons accommodate each other they have a line to tread which they cannot deviate from with prudence, much less with rectitude namely, that of cautiously guarding their own lands, without injuring those of their neighbours for a lawsuit may cost ten times the value of the sand banks and islets of gravel to be gained by dexterity of management.

4360. The operations for improving rivers have for their object that of preventing them from injuring their banks of accelerating their motion, and of lessening the space of ground which they occupy, or altering their site. These purposes are effected by piers or guardes for altering the direction of the current works for protecting the banks and by changing or deepening the river's course.

4361. The principles on which these operations are founded are chiefly two first, that water like every other body when it impinges on any surface, is reflected from it at a similar angle to that at which it approached it and, secondly that the current of water, other circumstances alike, is as the slope of the surface on which it runs. On the first of these principles is founded the application of piers for reflecting currents and on the second, that of straightening rivers, by which more slope is obtained in a given length of stream, and of course greater rapidity of motion obtained.

### SUBJECT 1. *Guarding River Banks.*

4362. A common cause of injury to the banks of rivers is produced during floods. A tree or branch carried down by a stream, and deposited, or accidentally fixed or retained, in its banks, will repel that part of the stream which strikes against it, and the impulse (counteracted more or less by the general current) will direct a substream against the opposite bank. The effect of this continual action against one point of the opposite bank is, to wear out a hole or breach, and immediately above this breach it is customary to place a protecting pier to receive the impulse of the substream, and reverberate it to the middle of the general stream. But if this pier is not placed very obliquely to the substream, as well as to the general stream, it will prove injurious to the opposite bank by directing a subcurrent there as great as the first and, indeed, it is next to impossible to avoid this so much so, that Smeston, in almost every instance in which he was consulted in cases of this sort, recommended removing the obstacle where that could be done, and then throwing loose stones into the breach.

4363. Injuries by floods according to Marshal, are to be remedied in two ways the one is to sheath the injured banks of the bays (fig 671 a, b c) with such materials

as will resist the circuitous current and let the river remain in its crooked state. The other to erect piers (d), to parry off the force of the current from the bank, and direct it forward with the twofold intention of preventing further mischief, and of bringing back the course of the river to its former state of straightness. It is to be observed, that the operation of guarding the immediate bank of a sharp river bend, against a heavy current meeting with great resistance, by sheathing it with stones, is generally a work of much

difficulty and expense, even where materials can be easily procured: while that of directing the current by a pier may frequently be accomplished at a comparatively small cost; and its effect be rendered infinitely more salutary and permanent. For it is plain that, if the accidental obstruction mentioned had been timely removed, no bad effect would have ensued and the river would have continued its direct course. Or if, through neglect, it had been suffered to remain awhile, until its mischief was discoverable; even then, if it had been moved from its station to the opposite side of the river, and placed in the part affected, this small counterpoise might have recovered the balance of the current, and directed it into its wonted channel, and, in almost any case, by judiciously placing, in a similar manner a pier or other obstruction proportioned to the magnitude of the power to be counteracted, the like effect may be produced.

4964. In the use of piers great caution is requisite, for a very little reflection will show that they are more likely to increase than to remedy the evil they are intended to cure. We have seen the injurious effects of such piers on the Tay and the Dee and on a part of the Jed near Crailing they are so numerous, that the stream is, to use a familiar phrase, handled about like a foot-ball, from one shore to the other behind every pier an eddy is formed, and if the stream does not strike the pier exactly, a breach in the bank takes place. Many of these piers have, in consequence, been taken down. The use of such piers can only be justified where the obstruction, from ill-neighbourhood or some such cause cannot be removed from the opposite bank, or where, as is sometimes the case, it arises from an island of sand or gravel thrown out by the river near its middle, which, however absurd it may appear the interested parties cannot agree as to who may remove. The case of buildings also being in danger may justify such a pier for immediate protection but if such breaches are taken in time, a few loads of loose stones dropped in the breach, as recommended by Smeaton, will effect a remedy without the risk of incurring or occasioning a greater evil.

4965. In the construction of piers, attention is required to secure the foundation either by first throwing in a quantity of loose stones, which the water will in a great measure dispose of so as to form a flat surface or by the use of piles either under or in single or double rows around, those parts of its base in contact with the river (Fig. 4965, a.) The elevation (b), where the current is not required to act with great violence on the opposite shore, ought to be bevelled back on all sides exposed to the water towards the middle of the structure (c). In the most important cases, stones are the only fit materials, and these

should be regularly joined and laid in cement according to the best practice of masonry. But, in general, a case of wicker work, of the proper shape, may be filled in with loose stones, some earth together with the roots of such plants as *Fusillago Potentilla*, *Spizum arvensis*, *Gilium*, &c. These will form a barrier of considerable durability for some years, and probably till the soil is so far subdued that, when the wicker case decays, its contents will have sufficiently consolidated to effect the object without further care. If not, the wicker case may be renewed. In ordinary cases, a wicker hedge projecting into the water will effect the object without further trouble.

4966. The abutment, or low-guard of loose stones, which Marshal recommends, and which, in effect, is the mode already mentioned (4962.) as preferred by Smeaton, is applicable to the following cases — First, where the river, in the part required to be bent, is confined, by rocks or otherwise, to an unalterable channel, as it frequently is in subalpine situations; and, secondly, where a deep pool occurs in that part, at low

water, so as to render it difficult to get a proper foundation for a pier. While the foot of the injured bank is covered with a pool at low water, shove off the brick of the bank, and shoot down loose stones from the top of it; suffering them to form their own slope, in the action of falling, and by the operation of succeeding floods continuing to pour them down, until the bank be secured, at least from minor floods, and then slope back the upper part, to give freedom to floods of greater magnitude.

4367. When the channel of a rapid river is narrow, and the banks undermined and washed away by the torrents, what Marshal terms the *land-guard* is to be used.

4368. In forming a *land-guard* for this purpose, he says, the foundation should be laid pretty deep, to guard against any accidental scoopings from the floods. The wall ought to be carried up dry, or with out mortar, the stones being laid with their ends outward, their inner ends pointing to the same centre like those of an arch, and to be locked with gravel, or earth, rammed in firmly behind, as the facing is carried up. The coping or uppermost course of the stones is to be securely bound, with thick tough rods (8 or 10 inches deep), whose surfaces, when beaten down, ought to lie even with that of the stone-work, and similar rods require to be laid, with a gently rising slope, until they unite smoothly with the natural turf of the land to be defended, so that the waters of floods, when they rise above the stonework, may have no obstructions to lay hold of, but may pass away smoothly over the surface of the land, as they commonly do over smooth greenland, without injury. Finally the stones are to be beaten firmly into the bank, with a rammer, a mallet, or a small battering-ram, adapted to the purpose, thus rendering the whole compact and firm, to resist the current. Where vacancies or fissures still appear, long splinters of stone are to be driven in, as wedges, to increase the firmness, and prevent the current from tearing out an unguarded stone. It follows, of course, that the largest and longest of the stones ought to be used where the greatest resistance is known to be required.

4369. The repairs of a *belemard* of the sort, like every other species of river fence, require to be attended to from time to time, especially after great floods. If the foundation be laid here, it requires to be re-covered with rough gravel, or with stones thrown loosely against it. If any of the facing stones be displaced or loosened, they are to be wedged in afresh, or their place supplied by others. Or if the turf which binds them at the top be disturbed, the torn part should be cut out square, and be firmly and completely filled up with fresh turves.

**SUBJECT 2. Changing the Courses of Rivers deepening their Beds, or raising their Waters to a higher Level.**

4570. A river whose course is in a straight line or nearly so, hardly ever makes any encroachment on its banks, except perhaps very large rivers, when they rise above their usual level, either by an increase in their own waters, or from their flow being in some degree interrupted by the tides. Hence, whenever a river is narrow in its channel and winds considerably, any mischief it commonly occasions may be prevented by deepening and straightening the course of the stream. (*Code of Agr.* p. 319.)

4571. The alteration of the course of a river or brook is attended with difficulty and expense, according to the particular circumstances. In a simple case, in which one straight cut only is required, the principal difficulty, and that which requires the best skill of the artist, lies in directing the current of the first flood, out of the old into the new channel; but if a bend of the old channel can be made use of, this difficulty may be said to vanish. The mouth of the new cut receives the current with a straight course consequently, if it be made of sufficient capacity the river, in a flood, can have no propensity left towards its old channel; and the loose materials which rise in forming the mouth of the new cut, will generally be sufficient to turn the stream at low water into it. But if a suitable bend cannot be approached by the new cut, a directing pier will be required to bend the flood current, and give it a straightforward course into the new channel; a watertight dam being formed between the point of the pier and the firm bank of the new channel to prevent the water from regaining its wonted course.

4572. An entirely new bed or channel, however is much to be preferred where it can be obtained for in an altered course, when the stream passes alternately through new soil and through a part of its old bed, its action on surfaces which are so different in regard to induration ends, if great care is not taken, in holes and gulleys in the new bank, which require to be constantly filled up with loose stones thrown in, and left to be fixed by the pressure and motion of the water. In the

case of a river passing near a house (fig. 673.) this is sometimes of great importance.

4573. Cutting the new channel is merely a work of manual labour, being attended with no other difficulty than what may arise from the expense, which will depend on the size of the river, the nature of the ground to be cut through, and the value of labour in the given district. It is mostly to be ascertained with sufficient accuracy by previous calculations. (See 2822.)

4574. The pier of the new cut, on account of its greater depth may be small, compared with that of the

old channel. For the current of floods, by carrying off the earth particles with which they come in contact, will soon enlarge it. It is nevertheless right to give ample room in the new channel, lest the first flood should prove high, and, by bursting its bounds, force its way back to its former course.

4573. If your river course requires to be carefully attended to, during a few years after it is opened, to see that its channel preserves its straightness, and that no breaches are made or threatened in its banks. Considering the uncertainty of extraordinary floods, it cannot be said to be out of danger in less than three years; hence it becomes prudent, when a work of this nature is contracted for, or undertaken to be done by measurement, at an estimated price or price previously agreed upon (as is generally ought) that the undertaker should agree to preserve the straightness of the channel, and uphold its banks during that or some other time fixed upon, and to deliver them up, at the end of the term, in the state and condition specified in the contract.

4574. At some of straightening the courses of a river is given in *The Code of Agriculture*. The waters, which in their crooked course were formerly almost stagnated, now run at the ordinary rate of the velocity given them. They never overflow their banks. Cattle can now pasture upon those grounds in which they would formerly have been swamped. The surface of the water being now in general four and sometimes six feet below that of the adjacent fields, this cut serves as a general drain to the whole valley, so that three hundred acres may be converted into arable land, sixty acres of moss may be improved into meadow, and five hundred acres of arable land are rendered of double their former value. (p. 312.)

4577. Raising rivers to a higher level. As rivers and streams may require to be

deepened for the purpose of drainage, so may their waters require to be raised for the purpose of irrigation, impelling machinery, or producing cascades or waterfalls for the purpose of ornament. Dams or weirs for this purpose should be constructed so as to form a segment of a circle across the bed of the stream, with the convex side pointing up the stream, and the ends abutting against a natural or artificial bank (fig. 674). By this construction, the force of the

water, however great, will be effectually resisted, and the structure remains secure. The greater the slope towards the upper side, the better, but the lower side should be nearly perpendicular, that the water may fall over it without coming in contact with the face of the building. (fig. 675)

The wall (a) should be built of regularly hewn stone, as should the abutments (b) next the wall there should be a mass of clay as a puddle (c), and above that gravel or earthy matter of any kind to a considerable slope (d). Beneath the dam a considerable portion ought to be paved (e). (*Gen. Rep Scot* vol ii. p. 669.)

4578. Banks, or banks of earth, for the confinement of water in artificial lakes or ponds, are often constructed at great expense, and, not being properly formed, often break out, and occasion considerable damage. The error in their construction is commonly owing to the want of breadth at the base in proportion to their height, and their not having a sufficient slope towards the water, nor a proper section of puddle in the centre. (*Ibid.*)

4579. Banks of loose stones of a large size (fig. 676.) may be had recourse to in slow

running rivers not subject to high floods, and where there is such a superabundance of water that no loss is sustained by the quantity which flows through the stones. Where it is required to retain the whole of the water, a puddle bank should be carried up the middle of the dam. (*Ibid.*)

### CHAP. III.

#### *Irrigation, or the Improvement of Culturable Lands and Farmeries by the means of Water.*

4580. The improvement of lands by water is of three kinds — irrigation, or the application of water to the surface of the soil, and especially of grass lands, as a species of culture; watering, or the covering of the soil with water to receive a deposition of earthy matter; and the procuring or preserving of water by wells, reservoirs, and other means, for the use of farmsteads, live stock in the fields, or the domestic purposes of the farmer or cottager.

### BOOK I. *Irrigation, or the Preparation of the Surface of Lands for the profitable Application of Water.*

4381 *Irrigation* in its different forms may be considered an operation of culture as well as of permanent improvement. It is accordingly in many cases effected by tenants, but always, as in the case of improving wastes, in consequence of extraordinary encouragement from the landlord, by long leases, money advanced, or other advantages.

4382. *The application of water to the surface of lands for the purpose of promoting vegetation* has been practised, as we have seen (141), from the earliest ages in warm countries. Solomon made *him gardens, and orchards, and pools of water to water therewith the wood that bringeth forth the trees.* (*Ecclesiastes.*) The art was taught by nature in the overflowing of the Nile and other rivers. Water is an essential article for the culture both of the cereal and pasture grasses, and indeed of most herbaceous crops, in all the tropical climates, and even in a great degree in the South of Europe. In the greater part of Italy and Spain, few crops are raised without being irrigated, and even in the south of France, potatoes, maize, madder, and sometimes vines, and orange trees, (as at Hieres,) have water applied to their roots, by furrows and other gutters and trenches formed on the surface. The system of watering grass lands was revived in Italy in the ninth century, and seems to have been practised in a few places in Britain from the time of the Romans; there being meadows near Salisbury which have been irrigated from time immemorial. In 1610, the public attention was called to it by Rowland Vaughan, in a work entitled, "*Most improved and long experienced Water Works,*" containing the manner of summer and winter drowning of meadow and pasture, by the advantage of the least river brook fount, or water mill adjacent, thereby to make those grounds (especially if they be dry) more fertile ten for one."

4383. *Irrigation in former times,* and in all countries, however imperfect, was probably much more frequent than it is now. In light and gravelly tracts of country the greatest difficulty in farming was to procure a sufficient supply of fodder for their cattle in winter. Meadows were therefore indispensable, and to increase the crop of hay, watering in a dry spring, and immediately (in dry summers) after the first crop was off, was constantly followed. Since the practice of sowing artificial grasses, and the introduction of the turnip husbandry the custom of watering has been in such situations given up not only because it has become less necessary than it was heretofore, but because *watered meadow hay is of inferior quality as well as value in the market.* It is nevertheless true that the herbage of very coarse boggy meadows is improved, and that of cold meagre soils is accelerated and increased by it.

4384. *But the principal scientific efforts in watering lands* have been made during the latter end of the last and beginning of the present century in consequence of a treatise on the subject by George Boswell, published in 1780, and various others by the Rev Thomas Wright, of Auld, in Northamptonshire, which appeared from 1789 to 1810. The practice, however has been chiefly confined to England, there being a sort of national prejudice, as Lock has observed (*Improvements on the Stafford Estates, &c.*), against the practice in Scotland, though its beneficial effects may be seen as far north as Sutherland, where rills on the sides of brown heathy mountains never fail to destroy the heath plants within their reach, and these are succeeded by a verdant surface of grasses. A valuable treatise on the subject of irrigation in Scotland, by Dr Singer will be found in *The General Report of Scotland*, vol. ii. p. 610. In England the best examples of watering are to be found in Gloucestershire and Wiltshire. In our view of this subject, we shall first consider the soils and situations suitable for irrigation, and next the different modes of effecting it, known as flooding, irrigating, warping, irrigation on arable lands, and subterraneous irrigation.

#### SUMMARY 1 *Soils and Situations suitable for Watering.*

4385 *The theory of the operation of water on lands* we have already developed. It appears to act as a medium of conveying food, as a stimulus, as a consolidator of mossy soils, as a destroyer of some descriptions of weeds or useless plants, and as the cause of warmth at one season, and of a refreshing coolness at another. From these circumstances, and also from what we observe in nature, there appears to be no soil or situation, nor any climate, in which watering grass-lands may not be of service; since the banks of streams between mountains of every description of rock, and in every temperature from that of Lapland to the equator, are found to produce the richest grass. One circumstance alone seems common to all situations, which is, that the lands must be drained either naturally or by art. The flat surfaces on every brook or river, after being covered with water during floods, are speedily dried when they subside, by the raising of the waters to their channel.

4386. *The most proper soils for being watered* are all those which are of a sandy or gravelly friable nature, as the improvement is not only immediate, but the effects more

powerful than on other descriptions of land. There are also some strong adherers to wet lands, such as are common in the vicinity of large rivers, which are also capable of being improved by watering; but the beneficial effects are not in such cases so soon produced as on the first sort, nor is the process so advantageous to the farmer, on account of the very great expense to which he must, in many cases, be put by previous draining. There are some other lands, as those which contain coarse vegetable productions, as heath, ling, rushes, &c. which may likewise be much improved by watering. It must be kept constantly in mind, in attempting this sort of improvement, that, the more tenacious the soil is, the greater should be the command of water for effecting the purpose as a stream, capable of watering fifteen or twenty acres of light dry land, would be found to be beneficial in but a small degree when applied to watering half the same quantity of cold clayey ground such as in its natural state abounds with coarse plants. On all soils of the latter kind a considerable body of water for the purpose of floating them is required to produce much benefit, and where a sufficient quantity cannot be procured this mode of improvement will seldom answer the farmer's intention or be advantageous in the result.

4387 *Smith, an experienced irrigator* supposes that "there are only a few soils to which irrigation may not be advantageously applied: his experience, he says, has determined, that the wettest land may be greatly improved by it, and also that it is equally beneficial to that which is dry." (*On Irrigation*, &c.) But, as many persons unacquainted with the nature of irrigation may be more inclined to the latter supposition than the former, he explains the reason of wet land being so capable of improvement from floating as that which is completely dry. It is, that, in the construction of all water meadows, particular care must be taken to render them perfectly dry when the business of floating shall terminate, and that the season for floating is in the winter and not in the summer, which those who are unacquainted with the process have too generally supposed. All peat bogs are certainly of vegetable origin, and these vegetables are all aquatic. It follows that the same water which has produced the vegetables of the bog would, under due management upon the surface, produce such grasses, or other vegetables, as are usually grown by the farmer, and he has hitherto had reason to think that this may be considered as a general rule for determining the situation of any experiments with water. The lands that permit of this sort of improvement with the most success are such as lie in low situations on the borders of brooks, streams, or rivers, or in sloping directions on the sides of hills.

4388. *The purity of the water to be used in irrigation* is supposed by some to be a matter of the first importance; but it is now fully proved, by the accurate experiments of an able chemist, and by the extraordinary growth of grasses in Prickley meadow, in Bedfordshire, that ferruginous waters are friendly to vegetation, when properly applied (*Smith's Observations on Irrigation*, p. 28.) Lead or copper never does good, and it is well known, that waters of that description, after they have been brought into fields, by levels cut at a considerable expense, have again been diverted, and suffered to flow in their original channels. Waters impregnated with the juices that flow from peat-mosses, are considered by many not worth applying to the soil. It is objected to them, that they are soon known, that they convey no material nutriment, and that they are commonly loaded with such noisette substances as, instead of promoting, will retard vegetation. (*Dr Singer's Vintner* p. 579.) It is urged, on the other hand, that a want of sufficient slope in the meadow or of proper management in regard to the water, may have occasioned the disappointments experienced in some cases, when bog-waters have been applied. (*Darlington Report*, vol. ii. p. 463.)

4389. *The advantages of watering lands* must, in a material degree depend on the climate. It is evident that the benefit to be derived from this process in Sweden, for example, where the summers are short, must be greatly inferior to what it is in Lombardy, where grass grows all the year, and that in Perthshire, where grass ceases to grow for at least three and often four months in the year, it must be much less than in Gloucestershire or Ireland, where its growth is not interrupted above a month or six weeks, and sometimes not at all: most grasses vegetating in a temperature of 33 or 34 degrees. Still, however, as the most luxuriant pastures are found on lands naturally watered, both in Sweden and Perthshire, it would appear worth while to imitate nature in cold as well as in warm countries. According to many writers on the subject, the benefits attending watering in England are immense. In Davis's *Survey of Wiltshire* it is calculated that 3000 acres of water meadow will, on a moderate estimate, produce, in four or five years, 10,000 tons of manure, and will keep in permanent fertility 400 acres per annum of arable land.

4390. *Watering poor land, especially if of a gravelly nature, is stated in The Code of Agriculture to be by far the easiest, cheapest, and most effectual mode of improving it.* "Land, when once improved by irrigation, is put in a state of perpetual fertility without any occasion for manure, or trouble of weeding, or any other material expense. It becomes so productive, as to yield the largest bulk of hay, besides abundance of the very best support for cows and lambs in the spring, and for cows and other cattle in the autumn of every year. In favourable situations, it produces very early grass in the spring, when it is doubly valuable; and not only is the land thus rendered fertile, without having any occasion for manure, but it produces food for animals, which is converted into manure, to be used on other lands, thus supplying, in a continued succession, that great source of fertility." Were these advantages more generally known, or more fully appreciated, a small portion of the kingdom might become like South Carmy, in Gloucestershire, where every spring, as it were, becomes subservient to the purpose of irrigation, fertilizing, in proportion to its size, either a small quantity or a large tract of land. (*Gloucestershire Report*, p. 180.)

4391. *Irrigation by liquid manure* may occasionally be practised in the neighbourhood of towns and cities to the greatest advantage. In the neighbourhood of Edinburgh, we

are intersected by Saphane, upwards of 900 acres are so irrigated from the principal common sewer, and that, although the formation of these meadows is irregular, and the management very imperfect, the effects of the water are astonishing: they produce crops of grass not to be equalled, being cut from four to six times a year, and the grass given green to milch cows.

**SUMMARY. 2. Implements made Use of in Watering Lands; and the Terms of Art peculiar to such Operations.**

4392. The principal instruments made use of in the preparation of lands for watering are the following:—

4393. The level, of which different descriptions have already been given, is necessarily employed to take the level of the land at a distance, compared with the part of the river &c. whence it is intended to bring the water, to know whether it can or cannot be made to flow to the part intended to be watered. Bringing the water after them to work by is found very useful in undertakings of this nature, especially when on a large scale, though the workmen too frequently dispense with it. In drawing a main, they begin at the head, and work deep enough to have the water to follow them, and in drawing a tall dam, they begin at the lower end of it, and work upwards, to let the water come after them. The level should, however, be made use of, as being more certain and correct.

Brown, an experienced irrigator in the west of England, recommends a level (fig. 677 a), which when not in use may be closed (b) like a walking stick. There is also a compass level (fig. 678), which may be used in the same way.

4394. A line and reel, and a breast plough, or turf spade (fig. 511) are likewise absolutely necessary. The use of the two former are well known: but as the line is mostly used in the wet, it should be this purpose be larger and stronger than those employed in a garden. The turf spade should be of the best description, being principally employed in cutting turfs for the sides of the channels.

4395. The spade made use of in this sort of work (fig. 678.) should have the stems considerably more crooked than those of any other kind: the bet

being of iron about a foot wide in the middle, terminating in a point, a thick ridge running perpendicularly down the middle, from the stem almost to the point: the edges on both sides should be drawn very thin, and as they are obliged to be kept very sharp, they should be often ground and whetted. This necessarily wears them away: and they soon become narrow: they are then used for the narrow trenches and drains, whilst new ones are used for the wider. From the stems being made crooked, the workmen, standing in the working position in the bottom of the trench or drain, are enabled to make it quite smooth and even. Shovels of different forms (fig. 680. a, b) and a scoop for lifting water (c), are also requisite.

4396. The crescent (fig. 679. b) is a tool made like the gardener's edging iron, only much larger: having the form of a crescent, being very thin and well stocked, with a stem about three feet long, and a cross handle to bear upon. It is used for tracing out the sides of the main, trenches, drains, &c.

4397. The turf knife (fig. 681.) has a comb-like blade, with a tread for the foot (a) and a bent handle (b). It is used for the same purpose as the crescent, and by some preferred.

4398. Wheelbarrows also become necessary to remove the clods to flat places: they may be open, without sides or hinder parts.

4399. Wheelbarrows are likewise made use of where the ground is too soft to admit of wheelbarrows: and where clods require to be removed during the time the meadow is under water.

4400. Three-wheeled carts &c. are necessary when large quantities of earth are to be removed, particularly when it is carried to some distance.

4401. Scythes, of different sorts (fig. 682. a, b), are required to mow the weeds and grass, when the water is running in the trenches, drains, &c. The scythes (b) should be made light, and have long stems, to reach wherever the water is so deep that the workmen cannot work in it.

4402. Besides these, forks (c), and long four or six-tined hoes, are requisite to pull out the roots of the sedge, rushes, reeds, &c. which grow in the large mains and drains.

6403. *Short fence water-gate* being, having legs as to draw up half the length of the thigh, are used in the same way as the large ones, to which a quantity of hay is heaped down all round the legs, and the high wall behind, to resist the running water for a length of time.

6404. *The service made use of are various* —

6405. *A weir is an erection across a river, brook, rivulet, main, &c., made often of timber only some times of brick, or stone and timber, with from two to eight or ten throughs (openings) to let the water through, according to the breadth of the stream. Its height is always equal to the depth of the stream compared with the adjacent land. Its use is, when the barthen are all in their proper place, to stop the whole current, that the water may rise high enough to overflow the banks, and spread over the adjoining land, or by stopping the water in its natural course, to turn it through narrow cut for conveying it another way, to water some distant lands.*

6406. *A sluice (fig 683 a, b) is made exactly as a weir only it has but one through. For if there are more than one, it becomes a weir.*

6407. *A trunk is a covered sluice, being a necessary construction in all cases where two streams of water are to cross each other to serve as a bridge for that stream which is to pass over or under the other.*

6408. *A conveyance is a sort of small wooden or brick aqueduct, built open, for the purpose of carrying one stream over another and is the most expensive conveyance belonging to the business of watering.*

6409. *A drain sluice or drain trunk, signifies such as are placed in the lowest part of a main, as near to the head as a drain can be formed, and situated low enough to drain the main, &c. It is placed with the mouth at the bottom of the main, being let down into the bank and from its other end a drain is cut to communicate with the nearest trench-draw. It is a contrivance to carry off the leakage through the barthen when they are shut down, to convey the water to other grounds, or to repair the main, &c.*

6410. *Flashes (fig 683 c) are floodgates, variously constructed. A particular kind which has about a foot to take off so as to permit the water to flow over that much of the hatch where it appears to be useful in irrigation, has been employed, but is not found to answer. They are best when made whole. They may be made of any timber, but oak and elm are the best.*

6411. *Head main is a term used to signify a ditch drawn from the river rivulet, &c. to convey the water out of its usual course to water the lands laid out for that purpose, through the means of lesser mains and trenches. The head main is drawn of various breadths and depths, according to the quantity of land to be watered, as the length, or to the fall or descent of the land it is cut through. Smaller mains are frequently taken out of the head main, at, or nearly at, right angles, to which they are usually cut. They are much smaller than the head main, and thus constitute the only difference. The use of both the large and small mains is to feed with water the various trenches which branch out into all parts of the meadow. These smaller mains are by some called eartrages, but improperly for it is confounding them with the open trunk, called by that name, as seen above.*

6412. *The branch is a narrow shallow ditch for conveying the water out of the mains to feed the land. It ought always to be drawn in a straight line from angle to angle, with as few turnings as possible. It is never made deep, but the width is in proportion to the length it runs, and the breadth of the pans between it and the trench draw. It narrows gradually to the lower end.*

6413. *The trench draw is cut parallel to the trench and as deep, when necessary as the fall drain water will admit. It ought always to be cut, if possible, so as to come down to a firm stratum of sand, gravel, or clay if the latter a spade's depth into it will be of great advantage. Its use is to carry away the water immediately after it has run over the pans from the trench. It need not be drawn up to the head of the land, by five, six, or more yards, according to the nature of the soil. Its form is the reverse of the trench, being narrower at the head, or upper part, and gradually wider till it comes to the lower end and empties half into the tail drain.*

6414. *The tail drain is a receptacle for all the water that runs out of the other drains, not so situated as to empty themselves into the river, and therefore it should run nearly at right angles with the trenches, but, in general it is drawn in the lowest part of the ground, and used to convey the water out of the meadow where there is the greatest descent. Thus it is generally found in one of the fence ditches for which reason a fence ditch is mostly used, at once fencing the meadow and draining it.*

6415. *A pane of ground is that part of the meadow which lies between the trench and the trench draw, and is the part on which the grass grows that is mown for hay. It is watered by the trenches, and drained by the trench drains, consequently there is one on each side of every trench.*

6416. *A carry pane is that part of the ground which, in a properly watered meadow lies on that side of a main where no trenches are taken out. It is watered the whole length of the main over its banks, and a drain runs parallel with the main to drain the carry pane. Its use is to afford a road for conveying the hay out of the meadow, and prevent the teams from crossing all the trenches.*

6417. *A head is a stoppage made in various parts of these trenches where there is a quick descent. It is formed by leaving a narrow slip of ground across the trench where the head is intended to be, cutting continuously a wedge-shaped piece out of the middle of it. Its use is to check the water and force it over the trench into the pans. For if it were not for these heads, it would run rapidly on as the trench without slowing over this land as it passed along. The great art of watering meadows consists in giving to every part of each pane an equal quantity of water.*

6418. *A gutter is a small groove cut out from the tails of these trenches, where the pans run longer at one corner than the other. Its use is to carry the water to the extreme point of the pans. Those pans which are intersected by the trench and tail drain meeting in an obtuse angle, want the assistance of these gutters to convey the water to the lowest side, and when, from imperfect leveling, some parts of the pans lie higher than they made, a gutter is drawn from the trench over that high ground, which otherwise would not be overflowed. Without this precaution, unless the flats were filled up (which ought always to be done when materials can be had) the water would not rise upon it and after the watering season was past, these places would appear rusty and brown, whilst a rich verdure would overgrow the others, at the close, also, the grass in these places would be scarce high enough*

for the *seynes* to touch it, whilst that around them, which had been properly treated, would drain its luxuriance to down. Though this method of treating such places is mentioned, their existence ought always to be repudiated; for every inequality in water meadows should either be levelled down or filled up.

Here the *seynes*, however, in bringing the water over those places to which it could not rise of itself, and in carrying it off from others where it would otherwise stagnate.

4433. *Catch drains* is a term sometimes applied to a method made use of to irrigate the land when the water is strong, and the method is this: when a meadow is pretty long, and has a quick descent, the water is made to run swiftly down a drain or drains, in which it is stopped at different distances so as to spread it over the adjoining surface. (See Ag. 685. p. 755.)

4434. The *bed* of a river, main, trench, &c., is the bottom of it.

4441. *Food means* water standing upon the land, or in the tail drain, trench drains, &c., so as to saturate the ground near them; and is considered sometimes by the state not having been properly filled up and at other times, when, a water being shut close, to water some high ground above it, the water is thrown back upon the ground contiguous. In this case the lower soil, whichever it is, must be borne with.

4452. *A turn of water* means to turn land in a meadow as can be watered at one time. It is done by shutting down the hatches in all those weirs where the water is intended to be kept out, and opening those that are to let the water through. The quantity of land to be watered by one turn must vary with the size of the river main, &c. as well as with the plenty or scarcity of water.

4453. The *head of a meadow* is that part into which the river main, &c. first enters; and the tail of a meadow is that part out of which the river, &c. last issues.

4454. The *upper side of a main, or trench*, is that side which (when the main or trench is drawn at, or nearly at, right angles with the river, &c.) fronts the part whence the river entered. Consequently the lower side is the reverse.

4455. The *upper pane* in a meadow is that pane which lies upon the upper side of the main, or trench, drawn at right angles with the river, that is, when the river, &c. runs north and south, entering at the north, and the main and trenches are drawn east and west, all those panes which lie on the north side of the main, &c. are called the upper panes, those on the south side are called the lower. But it must be noticed, that where the mains, trenches, &c. run parallel with the river the panes on either side are not distinguished from each other.

4456. *Meadows are of two sorts*: flowing calculated for a flat country, and catch-work, for sloping grounds.

4457. *Flowing meadows*. Where the ground is flat, the soil is formed into beds, or broad ridges, like those met with at blackfolds. They are commonly from 30 to 40 feet wide and nine or ten paces in length; as, in such situations, the great object is, when once brought on, to be able to carry off the water quickly. Hence it is necessary to throw up the land in high ridges, with drains between them. More of the failure in irrigation arises from the ridges not being sufficiently high, and the slopes not being sufficiently steep, than from any other cause. (Code.)

4458. *Catch-work meadows*. It is difficult to give an intelligible written description of the mode of making these meadows. To be properly understood, the operation must be seen. It may however, in general be remarked, that the system is calculated for sloping grounds, and that, after the water is brought from the original stream, into a new cut, it is stopped at the end, on as high a level as the case admits of, by which means it is made to fill the trench, and run over at the side, flooding the land below. But as the water would soon cease to run equally, and would wash the land out in gutters, it has been found necessary to cut small parallel trenches, at the distance of from 30 to 50 feet, to catch the water again (hence the name originated) and the same plan of spreading or diffusing is continued, until the water reaches the main drain at the bottom of the meadow. It is a great advantage attending the catch-work system that it is not only less expensive, but the same quantity of water will do much more work. (Code.)

### SECT. 3. Preparation of Surfaces for Irrigation.

4429. *Artificial irrigation*, Smith observes, is produced by diverting the water of a brook out of its accustomed channel (where there is a fall) in such a manner that, the new watercourse being kept nearly level, the space between the old and new channel may be floated, the water being brought upon the land by the new channel and taken away by the old one. Thus a constant discharge and succession of water is maintained, without such an accumulation as would make it appear bright upon the land, or without such a deficiency as would leave any part of it not perfectly floating for the art of irrigation may be most properly called *floating, not soaking nor drowning*. Soaking the soil, similar to the effects produced from a shower of rain, is not sufficient for the general purposes of irrigation nor will damming up water, and keeping it stagnant upon the surface, like that in a pond, or on the fens, produce the desired effect.

4430. *Stagnating water on land* may properly be called *drowning*, because it drowns or covers all the grass, thereby rendering the plants beneath it in some degree aquatic, or the herbage disposed to make such a change whereas the herbage of a water meadow should, by the construction and good management of the latter, enjoy the full benefits of both the elements of air and water. Practice has proved that there is no better method of doing this than by keeping water passing over the surface of the land with a brisk current not so brisk as to wash away the soil, and yet in sufficient quantity to cover and nourish the roots, but not too much to hide the shoots of the grasses—hence appears the necessity of adjusting the quantity of water—and hence it also appears, that one main drain to bring the water on the upper side of the mead, and another on the lower side to take it away, will not be adequate to all the purposes of such an accurate regulation. If the space between the upper channel or main feeder and the lower one or main drain, should therefore be wider than is proper for the good adjustment of the water, that is, so that every part of the space shall have enough water passing over it and no part too much, then that space must be divided into smaller spaces by intermediate drains, which shall catch and re-distribute the water. As the water is brought by the main feeder upon the higher

side of a piece of ground which slopes towards the main drain, and down which sloping perhaps the water will run very readily, it does not, to persons unacquainted with irrigation, at first sight appear necessary to make such a number of intermediate catch feeders. But it is proved by experience, that, however regular the slope of ground may appear to the eye, the water will find a number of irregularities, forcing itself into gutters or channels, and defeating the purposes of irrigation; in the hollow places by excess, and in high ones by the want of water. Hence the water, which was scattered over the surface of the first space, being all collected in the catch drain, may by the skill of the floater be let out upon those parts of the bed below which appear to need the most assistance.

4431. *The work should always be well formed at first* in all cases of improvements of this nature. Temporary means of making dams and hatches to divert the water out of its usual channel may, says Smith, suffice to try an experiment, or for a tenant who has but a short term in the grounds to be irrigated; but every land-owner who enters upon such work in this temporary manner sadly mistakes his own interest. Indeed, it is frequently more difficult to repair than to renew upon large streams, when the foundations are often destroyed by the force of the water. The same principle holds good upon small streams, and even in the drains and feeders of a water meadow. Whenever the channels are so constructed as to make a fall, or much increase the rapidity of the stream, it is constantly disposed to wear away the sides of its channel, or undermine a dam. To repair these defects, land must be dug away and wasted each time it is replaced, with the loss of labour. The consequent ill management of the water renders it more advisable, and perhaps cheaper to make all such works of masonry. When works are well done at first, the owner ever finds much pleasure in viewing them, and even the labourers feel much more interested in their good management.

4432. *The expenses of making a water meadow* are not easily estimated. Much depends on the original state of the ground, the size and fall of the stream to be used, the cost of hatches, and length of the main feeders which may be necessary for diverting the water out of its original channel, and even upon the charge for levelling land, which differs materially. Some soils are much harder and more difficult to move than others, and, in certain situations, building materials are very scarce and dear. Thus last circumstance must make a considerable variation in the price of the hatches, where the stream is large. It is also impossible to tell, with any degree of certainty what proportion these expenses should bear to the quantity of land irrigated, for some situations will require much more masonry than others.

4433. *Before entering upon the execution of a water meadow* it is necessary to consider fully, whether the stream of water to be made use of will admit of a temporary wear or dam to be formed across it, so as to keep the water up to a proper level for covering the land without flooding or injuring other adjoining grounds: or if the water be in its natural state sufficiently high without a wear or dam or can be made so by taking it from the stream higher up more towards its source; and by the conductor keeping it up nearly to its level till it comes upon the meadow or other ground: and still further whether the water can be drawn off the meadow or other ground in as rapid a manner as it is brought on. Having, in addition to these, an attention to all such other difficulties and obstructions as may present themselves, from the lands being in lease, through which it may be necessary to cut or form the mains or grand carriers, from the water being necessary for turning mills, from the rivers or brooks not being wholly at the command of the irrigator, and from small necks of land intervening so as to prevent the work from being performed to the greatest advantage, the operator may be in a situation to commence his operations.

4434. *In order to have an equal distribution and prevent waste*, Smith states, that no part of a meadow, either in catch-work or beds, should be so formed as to be floated directly from the main feeder but all the main feeders should be kept high enough to discharge the water into the small feeders with considerable velocity and through a narrow opening. The motion of water is truly mechanical it requires a great deal of ingenuity, and a perfect knowledge of lines and levels, to make it move over the ground in a proper manner. No two pieces of land being exactly alike, renders it still more difficult to set out a water meadow, but even if the figure of two pieces be alike, the inequalities of surface will probably vary. Each meadow, therefore, requires a different design, unless the landowner makes up his mind to the heavy expenses of paring off banks, and filling up such hollows as may be necessary to reduce it to some regular method the construction to be varied according to the nature of the ground. This constitutes the difference between the water meadows of Berkshire and Devonshire. Those of the latter are upon small streams carried round the sides of the hills, and are chiefly catch-work; those of the former, being near large rivers and boggy ground, are thrown up into ridges to create a brisk motion in the water, and also for the essential purpose of draining off all superfluous moisture, which might be injurious to the grasses when shut up for feeding or mowing. Where there is much flooding to be done with a little water, or rather where the great fall of a small stream will admit of its being carried over a vast quantity of ground and used several times, it is desirable to employ it in such

a way as that the heavy particles it may contain may be deposited as equally as possible over the whole surface to be irrigated. But it is to be observed, that this mode of applying water must not be substituted as a perfect model. If it should answer the purpose of a coat of manure, upon such an extent of ground, it is all that can be expected, and will amply repay the expense. Losing fall is wasting water.

4426. The drains of a water-meadow require no greater despatch than is necessary to carry the water from the surface: therefore the water ought to be collected and used again at every thousand feet of the fall, if it be not catch-work. It is sometimes difficult to do this in best-work meads; but where the upper part of the meadow is catch-work or in level beds, and the lower part not too much elevated, it may be done. By collecting and using the water again in the same piece of ground before it falls into the brook, a set of hatches is saved, and it is not necessary to be very particular about getting the upper part into high ridges, since that part of the meadow which is near the hatches generally becomes the best, and the lower end of the field, being often the wettest or most boggy in its original state, requires to be thrown up the highest. If the land is of a dry absorbent nature before flooding, it is not necessary that it should be thrown up into high beds, but merely as much inclined as will give the water a current.

4427. Inclined planes are absolutely necessary for the purpose of dry-ditches. To form these between straight and parallel lines, it is necessary to dig away and where it is too high and move it to those places where it is too low to make such a uniformity of surface. The new-made ground will of course settle in hollows proportioned to the depth of loose matter which has been recently put together; but this settlement will not take place until the new soil has been completely soaked and dried again; therefore these defects cannot be remedied before the second or third year of watering. It will therefore require more skill to manage a water-meadow for the first three or four years, than afterwards.

4427. Properly to construct a water-meadow is much more difficult than is commonly imagined. It is no easy task to give an irregular surface that regular yet various figure which shall be fit for the overflowing of water. It is very necessary for the operator to have just ideas of levels, lines, and angles; a knowledge of superficial forms will not be sufficient: accurate notions of solid geometry (obtained from theory or practice) are absolutely necessary to put such a surface into the form proper for the reception of water, without the trouble and expense of doing much of the work twice over. (*Obs. on Irrigation, &c.*)

4428. As an example of irrigating a meadow from both sides of a river, we take the following one from

684

Rowell's treatise. From the upper part of the grounds, two main drains (a, a') are formed at right angles to the river, one running north, the other south, across the meadow to within about six yards of the fence ditches which surround it (b) and are used for that drains by means of these fence ditches the water is discharged into the river. A wear erected across the river forces the water into either of the main drains, which is done by shutting the other wear close. When there is not water enough, or it is not convenient to water both parts of the meadow at once, by shutting close one of the wears, the current is forced into that main whose wear is open, thence to be conveyed through the trenches over the panses, to water that side of the meadow: then by shutting that, and opening the other, the opposite main is filled, and by means of the trenches that side of the meadow is watered in the same manner, and lastly by shutting them both and opening the river wear, the water flows in its usual course, and the land on both sides is laid dry. From the main drains (a, a') the water flows along the highest part, or crowns of the ridges (c), and is carried off to the tail drains by the trench drains (d).

4429. As an example of an irregular surface watered from one side of a river, we shall have recourse to the same author. There is a wear

685

at a sluice (c) erected at the end of one of the small mains, to force the water into the branch trench opening (f), that being the highest ground.

NOTE: A very complete plan of Brigadier General (G. S. S.) was shown for the Daily of Mexico, by Smith, at  
 Friday. This note is signed from a house (A), to a main capital, with various conditions (G. S. S.) the

65

surface is formed into ridges (e, e), over which the water flows, and is carried off by the drains in their furrows (g, g), to the main drains (a, a), and to the brook at different places (f, f). There are bridges (c) over the main feeders, small arches over the main discharging drains (b), and three hatches (d).

4441. As an example of catch-way venturing, we may refer to a case (fig. 637) given in a recent work

687

[illegible]

these carried on what is termed horizontal or level gutters. In some places in Essex, it is the practice to irrigate during winter by means of the water of occasional floods. Sometimes this water is obtained from the ditches along the sides of the roads, and from the drainages of villages and in these cases is more or less enriched by earthy materials.

4442. *An example of the benefit of flooding*, we refer to Loch Ken, in Kircudbrightshire, the most striking instance known in Great Britain of advantage being derived from the inundation of a lake. At the head of this beautiful piece of water, there is a flat of about 240 statute acres, which is rendered, by flooding, one of the richest spots in Scotland. Many acres in it produce at the rate of three tons of hay each and some parts of it have been covered with grain for twenty-five years in succession, without any measure, except what it receives from the inundation it requires. These, however, have behind them a variety of enriching substances. (*Statistical Account of Scotland*, vol. IV. p. 520.)

4443. *Flooding upwards*. The ancient and now obsolete practice of flooding, or as it was termed, of flooding upwards, was practised in various parts of the kingdom. For that purpose, the water was penned, in tracts of floods, by means of a dam or floodgate across the bottom of the meadow or flat to be watered. The waters were not suffered to remain long upon the land, but were let off as soon as it was judged that they had deposited their sediment. The benefit arising from this method of using floodwaters, it is said, was considerable but when the improved mode of irrigation by floating ridges was introduced, and found more advantageous, the other was discontinued. (*Marshall's Midland Counties*, Minute 37.)

4444. *Watering land by machinery*. If the land be put in a proper form for irrigation, and supplied with a good stream at proper seasons, there can be no difference from the method of getting it on the surface, and if all other circumstances are equally favourable, the same fertility may be expected from water thrown up by a drain-mill, as from that which runs from a brook. (*Smith's Observations on Water Meadows*, &c. p. 93.) A cheap and effectual power for raising water in sufficient quantities to flow about ten acres at a time, would be an invaluable acquisition for a productive water meadow is probably the true mark of perfection in the management of a farm. (*Middleton Report*, p. 322.)

4445. *Sea water*. Smith suggests the idea of employing machinery to raise not only fresh but even sea water for irrigation (*Observations*, p. 87.) It is well known how much all kinds of stock are improved by salt marshes, and how beneficial to them is a moderate quantity of saline matter. There are many parts of the kingdom where, by the aid of machinery, these advantages might be obtained at a moderate expense. (*Code*.)

4446. *The expense of irrigation varies according to the nature of the work*. Where the catch-water system is practicable, in favourable situations, the farming may be done as low as ten shillings per acre. This fact is, in many cases, decisively in favour of this natural and simple mode, which requires also much less water, and often answers fully as well as flat flooding (*General Report*, vol. II. p. 598.) The expense of bed-work, as it is called, is, however, considerable. If the ground to be flooded be smooth on its surface, or in regular ridges, and if the water can easily be brought to the meadow with a temporary wear, supposing the extent to be almost twenty acres, it may be done at from 5*l.* to 10*l.* per acre but if the land be of large extent, with an irregular surface if a large conductor and a proper wear shall be required, with hatches both in it and also in the feeders and if the aid of a professional person, to lay out and oversee the work be necessary (which is generally the case), the expense will vary from 10*l.* to 20*l.* per acre. (*General Report*, vol. II. p. 598.) Nay, in Wiltshire, where they are anxious to have their meadows formed in the most perfect manner, with that regularity which the nice adjustment of water demands, the expense per acre has amounted to 40*l.* (*Smith's Observations on Irrigation*, p. 56.)

4447. *Objections to irrigation* have been made on the supposition that it renders a country unhealthy but as the water is continually kept in motion, this is not likely to be the case, and indeed is found not to be so in Gloucestershire, Leicestershire, and other places where it is extensively practised. It is also thought that though the produce may be increased, it becomes in a few years of so coarse a nature mixed with rushes and water plants, that cattle frequently refuse to eat it; and when they do, their appearance proclaims that it is far from being of a nutritious quality. (*Rutland Report*, p. 114.) But this objection is never applicable to meadows skilfully made and properly managed; and whenever the grasses are coarse, if intended for hay they should be cut earlier. Rushes and water plants are proof that the meadow lies too flat and is ill managed. (*Code*.)

4448. *The principal impediments to irrigation* are the claims of different individuals on one stream, as millers, canal owners, &c. the intermixture of property and interests; and the existence in some cases of adverse leases.

4449. *The formation and arrangement of surfaces for irrigation*, however simple in principle, is in practice one of the most difficult operations of agricultural improvement. Whoever, therefore, contemplates extensive and intricate works of this kind will find it desirable to call on the assistance of a professor and contractor of reputation. In Gloucestershire there are a class of men known as "flooders," who have under them a con-

going off men accustomed to every part of the work, and who accompany their chief to examine works in any part of the country

#### Sect. II. *Warping, or the Improvement of Land by muddy Water.*

4430. *Warping* is a mode of fertilising lands by depositing a coat of mud on their surface. This may be practised on the borders of large rivers and estuaries into which sea tides flow or where floods are frequent; provided, however, that in either case the waters contain alluvial matters in a state of suspension. According to the best information that can be obtained (*Marshall, in R. Soc. of York, 1788. Day, West Riding Report, p. 171*), warping was first practised on the banks of the Humber, by one Barker, a small farmer at Rawcliffe, between 1730 and 1740: it was afterwards extended by Richard Jennings, of Armin, near Howden, in 1743, but, till about the year 1753, it was not attempted by any other person. It was first brought into notice by Marshall, in 1783, and subsequently in the *Report of the West Riding of Yorkshire* and is now practised by various proprietors and farmers on the Humber, the Trent, and other rivers. It has been long practised in Italy in a manner something different from that employed in this country. It may be considered as of Egyptian origin.

4451. *The theory of warping* is thus given by Arthur Young —

4452. *The water of the tides* that come up the Trent, Ouse, Don, and other rivers which empty themselves into the great estuary of the Humber, is muddy to an excess inasmuch that in summer if a cylindrical glass, twelve or fifteen inches long, be filled with them, it will presently deposit an inch and sometimes more, of what is called warp. Where this warp comes from is a dispute. The Humber, at its mouth, is clear water, and no floods in the countries washed by the warp rivers bring it, but, on the contrary do much mischief by spoiling the warp. In the very driest seasons and longest droughts, it is best and most plentiful. The improvement is perfectly simple and consists in nothing more than letting in the tide of high water to deposit the warp, and permitting it to run off again as the tide falls. This is the aim and effect, but to render it efficacious, the water must be at command, to keep it out and let it in at pleasure, so that there must not only be a cut or canal made to join the river, but a sluice at the mouth to open or shut, as wanted, and that the water may be of a greater depth on the land to be warped, and also prevented from flowing over contiguous lands, whether cultivated or not, banks are raised around the field to be warped, from three or four to six or seven feet high, according to circumstances. Thus, if the tract be large, the canal which takes the water and which, as in irrigation, might be called the grand carrier, may be made several miles long. It has been tried as far as four so as to warp the lands on each side the whole way and lateral cuts made in any direction for the same purpose. Observing, however that the effect lasts as long as you recede from the river — that is, it demands long time to deposit warp enough for producing benefit.

4453. *The effect of warping* is very different from that of irrigation: for it is not the water that works the effect, but the mud, so that in floods and in winter the business ceases; and it is not the object to manure the soil, but to create it. The nature of the land intended to be warped is not of the smallest consequence, bog, clay, sand, and peat, are alike eligible, as the warp raises it in one summer from six to sixteen inches thick, and in the hollows or low places, two, three, or four feet, so as to leave the whole piece level. Thus a soil of any depth you please is formed, which consists of mud of a vast fertility though containing not much besides sand and gravel.

4454. *The method of executing the work* is described in the following manner by Lord Hawke, in *The Agricultural Survey of the West Riding of Yorkshire* —

4455. *The land to be warped* must be banked round against the river. The banks are made of the earth taken on the spot from the land. They must slope six feet, that is, three feet on each side of the top or crown of the bank, for every foot perpendicular of rise: their top or crown is broader or narrower according to the impetuosity of the tide, and the weight and quantity of water; and it extends from two feet to twelve: their height is regulated by the height to which the spring tides flow, so as to exclude or let them in at pleasure. In these banks, there are more or fewer openings, according to the size of the ground to be warped, and to the choice of the occupier; but in general they have only two sluices — one called the floodgate, to admit, the other called the clough, to let off the water gently: there are enough for ten or fifteen acres. When the spring tide begins to rise, the floodgate is opened to admit the tide, the clough having been previously shut by the weight of the water brought up the river by the flow of the tide. As the tide subsides down the river, the weight or pressure of water being taken from the outside of the clough next the river, the tide water that has been previously admitted by the floodgate opens the clough again, and discharges itself slowly but constantly through it. The cloughs are walled on each side, and so constructed as to let the water run off, between the tide and the flow of the next, and to this point particular attention is paid. The floodgates are placed so high as only to let in the spring tides when opened: they are placed above the level of the common tides. Willows are also occasionally planted on the front of the banks, to break the force of the tides, and defend the banks by raising the front of them with warp then collected and accumulated; but these willows must never be planted on the banks, as they would destroy them by giving the waste power to shake them.

4456. *The season for warping* begins in the month of July, and continues during the summer, and as this sort of business can only be performed at that season, every occasion of having it executed should be embraced, by having the work in perfect repair, that every tide may be made to produce its full effect. With regard to the advantage of doing this work in the summer months, it may be remarked that at these times the lands not only become the soonest dry, a circumstance which must always fully take place before the process of fertilisation can be carried on; but the tides are less mixed with fresh water, in which condition they are constantly found the most effectual.

4457. *The expense of this mode of improving lands* must differ much in different cases, according to the circumstances of situation and distance vary; but it can seldom exceed

12, or 15, the acre, according to Young, and in most instances it must be greatly below such estimates.

4458. That no estimate can be made without viewing the situation of the lands to be warped, and the course and distance it will be necessary to carry the warp to such lands, is remarked by Day, in the *Agricultural Survey of the same district*. 14. The situation of the lands must be considered; 24. The quantity of land the same drains and ditches will be sufficient to warp; 34. The expense of building the ditches, cutting the drains, embanking the lands, &c. An estimate of these expenses being made, it will then be necessary to know the number of acres each ditch and drain will warp, before any estimate can be made as the greater the quantity of land the same ditches and drains will warp, the lighter the expense will be per acre. In Day's opinion, there is a great deal of land in the country capable of being warped at so small an expense as from 4l. to 8l. per acre, which is nothing in comparison to the advantages which arise from it. He has known land raised in value by warping, from 8l. to upwards of 40l. and 60l. per acre. The greatest advantages arise upon the worst land, and the more porous the soil the better as the wet filters through, and it sooner becomes fit for use. The advantages of warping are very great as, after lands have been properly warped, they are so enriched thereby that they will bring very large crops for several years afterwards without any manure, and when it is necessary the lands might be warped again at a very trifling expense, by opening the old drains, and would bring crops in succession five many years, with very little or no tillage at all, if the lands were kept free from quick grass and other weeds, which must be the case in all properly managed lands besides, the drains which are made for the purpose of warping are the best drains that can be constructed for draining the lands at the time they are not used for warping, which is another very great advantage in low lands.

4459. The best mode of cultivating now-warped land must depend principally on the nature of the warp and of the subsoil. In the *Code of Agriculture* it is recommended to sow it with clover, and to let it lie under that crop for two years, in order that it may be brought into a state fit for corn. Even though fallowed, it does not answer to sow land with wheat immediately after it is warped, but after white or red clover for two years, a good crop of wheat may generally be relied on. Nor is it proper, when land is warped, to plant it with potatoes, or to sow it with flax, being at first of too cold a nature though, if the land be not too strong for potatoes, these crops may answer, after it has been for two or three years in cultivation. In the quality of warped land, there are most essential differences, some will be very strong, and in the same field some will be very friable. The land nearest the drain is in general the lightest, owing to the quantity of sand that is deposited as soon as the water enters the field the land farthest from the drain is in general the best. The produce of warped land varies much, but in general it may be stated as abundant. (*Code*, 315)

#### SUBJECT 1 Irrigation of Arable Lands, and Subterraneous Irrigation.

4460. The irrigation of arable lands is universal in warm countries, and even in the south of France and Italy. The land is laid into narrow beds, between which the water is introduced in furrows during the growth of the crop, and absorbed by the soil. In other cases the crop is grown in drills, and the water introduced in the furrow between each row. In this mode of irrigation no collecting drains are required, as the whole of the water laid on is absorbed by the soil. The principal expense of the operation is that of preparing the lands by throwing the surface into a proper level or levels. The main or carrier is conducted to the higher part of the field, and the rest is easy. A particular description of the practice, as carried on in Tuscany is given by Sigismundi. (*Agr de la Toscane*.) Some account also of the practice in Italy and the East Indies will be found in our outline of the agriculture of these countries. (267 and 281.) In the *General Report of Scotland*, vol. iii. p. 361 it is stated, that a field of waste land, which had been flooded during winter with stagnant water, was thus, without manure, rendered capable of yielding a good crop of oats but this is more of the nature of warping than of that description of irrigation which is practised in warm countries on arable lands, during the growth of the crop.

4461. Subterraneous irrigation appears to have been first practised in Lombardy and first treated of by Professor Thouin (*Annales du Musée &c.*) It consists in saturating a soil with water from below, instead of from the surface, and is effected by surrounding a piece of ground by an open drain or main, and intersecting it by covered drains communicating with this main. If the field is on a level, as in most cases where the practice is adopted in Lombardy nothing is more necessary than to fill the main, and keep it full till the lands have been sufficiently soaked but if it lies on a slope, then the lower ends of the drains must be closely stopped, and the water admitted only into the main on the upper side: this main must be kept full till the land is soaked, when the mouths of the lower drains may be opened to carry off the superfluous water. The practice is applicable either to pasture or arable lands.

4462. In Britain, subterraneous irrigation has been applied in a very simple manner to drained bogs and morasses, and to fen lands. All that is necessary is to build a sluice in the lower part of the main drain where it quits the drained grounds, and in dry weather to shut down this sluice, so as to dam up the water and throw it back into all the minor open drains, and also into the covered drains. This plan has been adopted with success, first, as we believe, by Smith, of Swinbridge Mus, in Ayrshire, and subsequently by Johnston, in the case of several bog drainages executed by him in Scotland;

On clayey soils very little cover is necessary than extending the surface of the excavation, and perhaps watering it and binding it to a smooth surface with runners. The pond being now formed, the next operation is to coat it over with coarse gravel to the depth of at least eighteen inches, or, what is preferable, chalk and flint with gravel; or, best of all, to masonry or pave it. It is also very desirable to pave or gravel the surface for the breadth of at least two yards round the pond, in order to prevent the cattle from pecking it when they come to drink.

whereas a pond sloped on all sides may supply four fields, or even a greater number. (Ag 680.)

6875. The Gloucestershire ponds are made either of a square or a circular shape and generally so situated as to furnish a supply to four fields. (Ag 680.) Three layers of clay, free from the smallest stone or gravel, are so worked by as to form an impenetrable cement. The whole is afterwards covered with sand, and finished with pavement. (Gloucestershire Report 4, p. 31.)

6476 The Derbyshire artificial meers or cattle ponds, are made in their dry rocky pastures, with great success. Having selected a low situation for the purpose, they form an excavation ten or twenty yards across, and spread over the whole a layer about five inches thick, of refuse shales lime and coal cinders. Then they spread trample, and run down a stratum of well tempered clay about four inches thick and upon this they spread a second bed of clay, in a similar manner, of the same thickness. The whole of the bottom and edges of the meers is then paved with rubble stones, and small rubble stones, several inches thick, are spread upon the pavement. (Derbyshire Report, vol 1, p. 604.)

6475 The situation of field ponds, where practicable, should be at the intersection of fences, so that one may serve as many fields as possible. This, however cannot be the best situation in every case, because it may happen that water cannot there be collected. At the same time a low situation is not always desirable, because it may be so circumstanced that too much dirty water may run into it during rains.

6476 Trees are frequently planted round ponds and with seeming propriety as their effect is beautiful, and they shade the water from the direct influence of the sun during summer but in autumn their leaves certainly tend to render the water impure for a time. As most leaves are of an stringent quality perhaps there may be no injury sustained by cattle from drinking such water at first but after some time the leaves begin to decay and occasion a sort of fermentation, which till it subsides in the beginning of frosty weather, renders the water somewhat unwholesome and very unsightly. Leaves therefore ought to be drawn off with long open rakes as they fall from the trees.

4477 Wells, where no better method of procuring water can be devised, may be resorted to, both for fields and farmhouses but the great objection to them is the labour required to pump up or otherwise raise the water, and the consequent risk of neglect. Before proceeding to dig a well, it ought first to be determined on whether a mere reservoir for the water which oozes out of the surface soil is desired or obtainable, or a perpetual spring. If the former is the object in view a depth of fifteen or twenty feet may probably suffice, though this cannot be expected to afford a constant supply unless a watery vein or spring is hit on. If the latter, the depth may be very various, there being instances of 800 and 500 feet having been cut through before a permanent supply of water was found. (Middlesex, Surrey, and Hampshire Reports.)

4478 The art of well-digging is generally carried on by persons who devote themselves exclusively to that department. The man being fixed on, the ground plan is a circle generally of not more than six or eight feet in diameter. The digger then works down by means of a small short-handled spade, and a small implement of the pick-one kind. The earthy materials being drawn up in buckets by the hand or a windlass, the employed, then usually manages the whole of the work, bricking round the sides with great dexterity and readiness, but in other cases it will be necessary to have a bricklayer to execute this part of the business.

4479 Method. There are two methods of building the stone or brick within the well, which is called the shoring. In one of these a circular ring is formed of the same diameter as the intended well, and the timber of which it is composed is of the size of the brick courses with which the well is to be lined. The lower edge of this circle is made sharp, and shod with iron, so that it has a tendency to cut into the ground. This circular curb is placed flat upon the ground, and the bricks are built upon it to a considerable height, like a circular wall. The well-digger puts within this circle, and close away the south of the bucket, the weight of the wall then forces the curb and the brickwork with which it is lined in deeper into the earth, and as fast as the earth is removed it sinks deeper. The circular brick wall being increased or raised at top as fast as it sinks down but when it gets very deep, it will sink no longer, particularly if

it passes through soft strata; in this case, a second kind of a smaller stone is sometimes begun within the first. A second kind will not sink from the bottom of the shaft, or when it is required to stop out water, the intermediate stones must be laid one by one at the bottom of the work, taking care that the work is not left unprotected in such a manner as to let the bricks fall as they are laid; this is called under-sinking.

4480. *Stones etc.* Well-diggers sometimes experience great difficulty from a surface air which fills the well, and suffocates them if they breathe it. The usual mode of clearing wells of noxious air is, by means of a large pair of bellows, and a long leather pipe, which is hung down into the well to the bottom and blown out down by working the bellows.

4481. The test of the sugar is common in well-digging, both in ascertaining before commencement the nature of the strata to be dug into, and also in course of digging for the same purpose and because, by boring in the bottom of a well to a considerable depth, the spring is sometimes filled upon, and digging rendered no longer necessary.

4482. The use of the borer above may procure an adequate supply of water in particular situations. This mode appears to have been long restricted to in this and other countries. From what we have already stated as to the disposition of strata, the conditions requisite for its success will be readily conceived; viz. watery strata connected with others on a higher level: the pressure of the water contained in the higher parts of such strata on that in the lower will readily force up the latter through any orifice, however small. All that is necessary, therefore, is to bore down to the stratum containing the water, and, having completed the bore, to insert a pipe, which may either be left to overflow into a cistern, or it may terminate in a pump. In many cases, water may be found in this way and yet not in sufficient quantity and hence to rise to the surface; in such cases a well may be sunk to a certain depth, and the sugar-hole made, and the pipe inserted in it in the bottom of the well. From the bottom it may be pumped up to the surface by any of the usual means.

4483. *An example of well-digging combined with boring* we give that of a well dug at a brewery at Chelsea, Middlesex, in 1703. The stratum was within 30 or 35 feet of the edge of the Thames, and the depth 200 feet, mostly through a blue clay or marl. At the depth of nearly fifty feet a quantity of loose coal, twelve inches in thickness, was discovered; and a little sand and gravel was found about the same depth. The well-digger usually bored about ten, fifteen, or twenty feet at a time lower than his work as he went on; and on the last boring, when the rod was about fifteen feet below the bottom of the well, the men felt, as the first signal of water a rolling motion, something like the gentle motion of a coach passing over pavement. Upon his continuing to bore, the water presently pushed its way by the side of the auger with great force, scarcely allowing him time to withdraw the borer but that and his other tools into the bucket, and he drew up to the top of the well. The water soon rose to the height of two hundred feet.

4484. In a case which occurred in digging a well at Dr. Doreen's, near Datchet, the water rose to such a height above the surface of the ground, that, by confining it in a tube, he raised it to the upper part of the house. (*Rees's Cyclopædia*, art. *Well*, and *Darbyshire Rep.*)

4485. The process of boring the earth for spring water has of late been practised, with great success, in various parts of England, chiefly by a person named Goode, of Hantsington. In the neighbourhood of London, many fountains of pure spring water have lately been obtained by these means. We may particularly name those at Tottenham, Middlesex, and Mitcham, Surrey, both of which afford a continuous and abundant flow of water, at one time equal to about eight gallons per minute, but now reduced to a much smaller quantity, in consequence of the great number of holes that have been bored into the supplying strata.

4486. The operation of boring for water (fig. 691.) is thus performed. — The situation of the intended well being determined on, a circular hole is generally dug in the ground, about six or eight feet deep, and five or six feet wide. In the centre of this hole, the boring is carried on by two workmen, assisted by a labourer above (fig. 691.) The implements used may either be those of Goode, already described (fig. 3507) as the best, or any other instruments in repute. For variety's sake, we shall here describe the process by the instruments formerly in most general use about London. The handle (fig. 691 a) having a female screw in the bottom of its iron shank, a wooden bar or rail passing through the socket of the shank, and a ring at top, is the general agent, to which all the boring implements are to be attached. A chisel (b) is first employed, and connected to this handle by its screw at top. If the ground is tolerably soft, the weight of the two workmen, bearing upon the cross-bar and occasionally forcing it round, will soon cause the chisel to penetrate; but if the ground is hard or strong, the workmen strike the chisel down with repeated blows, so as to pick their way often changing their situation by walking round, which breaks the stone, or other hard substance, that may happen to obstruct its progress.

4487. The labour is very considerably reduced by means of an elastic wooden pole placed horizontally over the well, from which a chain is brought down, and attached to the ring of the handle. This pole is usually made flat at one end as a fulcrum, by being set into a heap of heavy loose stones; at the other end the labourer gives it a slight up and down vibrating motion, corresponding to the beating motion of the workmen below.

by which means the elasticity of the pole in rising lifts the handle and picket, and thereby very considerably diminishes the labour of the workmen.

4488. When the hole has been thus opened by a chisel, as far as its length would permit, the chisel is withdrawn, and a sort of cylindrical auger (c) attached to the

handle (a), for the purpose of drawing up the dirt or broken stones, which have been disturbed by the chisel. A section of this auger (d) shows the internal valve. The auger being introduced into the hole, and turned round by the workmen, the dirt or broken stones will pass through the aperture at bottom (shown at e), and fill the cylinder which is then drawn up, and discharged at the top of the auger, the valve preventing its escape at bottom.

4489. In order to penetrate deeper into the ground, an iron rod (f) is now to be attached to the chisel (b), by screwing on to its upper end, and the rod is also fastened to the handle (a) by screwing into

its socket. The chisel having thus become lengthened by the addition of the rod, is again introduced into the hole, and the operation of picking or forcing it down is carried on by the workmen as before. When the ground has been thus perforated, as far as the chisel and its rod will reach, they must be withdrawn, in order again to introduce the auger (c) to collect and bring up the rubbish, which is done by attaching it to the iron rod, in place of the chisel. Thus, as the hole becomes deepened, other lengths of iron rods are added, by connecting them together (f and g when joined form h). The necessity of frequently withdrawing the rods from the hole, in order to collect the mud, stones, or rubbish, and the great friction produced by the rubbing of the tools against its sides, as well as the lengths of rods augmenting in the progress of the operation, sometimes to the extent of several hundred feet, render it extremely inconvenient, if not impossible, to raise them by hand. A tripodal standard is therefore generally constructed, by three scaffolding poles tied together over the hole (fig 691) from the centre of which a wheel and axle, or a pair of pulley blocks, are suspended for the purpose of hauling up the rods, and from which hangs a forked hook (s). This forked hook is to be brought down under the shoulder near the top of each rod, and made fast to it by passing a pin through two little holes in the claws. The rods are thus drawn up, about seven feet at a time, which is the usual distance between each joint, and at every haul a fork (k) is laid horizontally over the hole, with the shoulders of the lower rod resting between its claws, by which means the rods are prevented from sinking down into the hole again, while the upper length is unscrewed and removed. In attaching and detaching these lengths of rod, a wrench (l) is employed, by which they are turned round, and the screws forced up to their firm bearing.

4490. The boring is sometimes performed for the first sixty or a hundred feet, by a chisel of two and a half inches wide, and cleared out by a gouge of two and a quarter diameter and then the hole is widened by another tool (m). This is merely a chisel, four inches wide, but with a guide (n) put on at its lower part, for the purpose of keeping it in a perpendicular direction the lower part is not intended to pick, but to pass down the hole previously made, while the sides of the chisel operate in enlarging the hole to four inches. This process, however, is generally performed at one operation, by a chisel four inches wide (b) and a gouge of three inches and three quarters (c).

4491. Placing and replacing the lengths of rod is done every time that the auger is required to be introduced or withdrawn; and it is obvious that this must of itself be extremely troublesome, independently of the labour of boring; but yet the operation proceeds, when no unpropitious circumstances attend it, with a facility almost incredible. Sometimes, however, rocks intercept the way which require great labour to penetrate, but this is always effected by picking, which slowly pulverizes the stone. The most

unpleasant circumstance attendant upon this business is, the accidental breaking of a rod in the hole, which sometimes causes a delay of many days, and an incalculable loss in drawing up the lower portion.

4482. When the water is obtained in such quantities and of such quality as may be required, the hole is finished or finished by passing down it the diamond chisel (c) this is to make the side smooth previously to putting in the pipe. This chisel is attached to rods, and to the handle, as before described; and in its descent the workmen continually walk round, by which the hole is made smooth and cylindrical. In the progress of the boring, frequent veins of water are passed through; but as these are small streams, and perhaps impregnated with mineral substances, the operation is carried on until an aperture is made into a main spring, which will flow up to the surface of the earth. This must, of course, depend upon the level of its source, which, if in a neighbouring hill, will frequently cause the water to rise up and produce a continued fountain. But if the altitude of the distant spring happens to be below the level of the surface of the ground where the boring is effected, it sometimes happens that a well of considerable capacity is obliged to be dug down so that level, in order to form a reservoir, into which the water may flow, and from which it must be raised by a pump: while, in the former instance, a continued fountain may be obtained. Hence, it will always be a matter of doubt, in level countries, whether water can be procured which would flow near to or over the surface. If this cannot be effected, the process of boring will be of little or no advantage, except as an experiment to ascertain the fact.

4493. In order to keep the strata pure and uncontaminated with mineral springs, the hole is cased for a considerable depth with a metallic pipe, about a quarter of an inch smaller than the bore. This is generally made of tin (though sometimes of copper or lead), in convenient lengths and as each length is let down, it is held by a shoulder resting in a fork, while another length is soldered to it, by which means a continued pipe is carried through the bore as far as may be found necessary, to exclude land-springs, and to prevent loose earth or sand from falling in and choking the aperture. (*Newton's Journal*, vol. vi. p. 146.)

4494. The manner of forcing down lengths of cast-iron pipe, after the bore is formed, is this:—The pipe (fig. 693. a) has a socket in its upper end, in which a block of wood (b) is inserted. From this block a rod (c) extends upwards, upon which a weight (d) slides. To the weight (d) cords are attached, reaching to the top of the bore, where the workman alternately raises the weight and lets it fall, which, by striking upon the block (b), beats down the pipe by a succession of strokes; and when one length of pipe has by these means been forced down, another length is introduced into the socket of the former. Another tool for the same purpose (fig. 694.) is formed like an acorn, the point of the acorn strikes against the edge of the pipe, and by that means it is forced down the bore.

4495. Wrought-iron, copper, tin, and lead pipes, are occasionally used for lining the bore; and as these are subject to bends and bruises, it is necessary to introduce tools

695

for the purpose of straightening their sides. One of these tools (fig. 695. a) is a bow, and is to be passed down the inside of the pipe, in order to press out any dents. Another tool for the same purpose (b) is a double bow, and may be turned round in the pipe for the purpose of straightening it all the way down. A pair of claws (c) is used for turning the pipe round in the hole while driving.

4496. In raising pipes, it is necessary to introduce a tool to the inside of the pipe, by which it will be held fast. The pine-apple stool for this purpose (d) has its surface cut like a rasp, which passes easily down into the pipe, but catches as it is drawn up, and by that means brings the pipe with it. There is a spear for the same purpose (fig. 696) which easily enters the pipe by springing; at the ends of its prongs there are flukes which stick into the metal as it is drawn up, and thereby raise it.

696

4497. Mr. Goad suggests the employment of long buckets with valves opening upward in their bottoms, for the purpose of drawing water from these wells when the water will not flow over the surface; also lift-pumps, with a succession of buckets, for the same purpose. (*Newton's Journal*, vol. viii. p. 249.)

4499. *Monmon has invented a new apparatus for guiding the operation of boring, which seems very ingenious; but we are not aware that it has yet been adopted in practice. Engravings, accompanied by a copious description, will be found in the Mechanics Magazine, vol. iv; in which work are also various other articles on the same subject.*

5000. *Of the various modes of raising water from deep wells, the pump is the most convenient, and the lever bucket the most simple. When a constant supply is wanted from a very deep well, machinery (fig. 697.) may be erected over it, and driven by an old horse or ass. While one bucket is filling, the*

other is emptying. In order to effect the filling of the bucket, the handle (b), which is of iron, is attached by iron rivets, on which it readily turns, below the centre of gravity of the bucket (c). In order that it may empty itself, a horizontal handle (d) is attached, which, when the filled bucket attains a certain height, is caught by a hook (e) fixed in the trough which conveys away the water raised (f). The horse or ass may be made to work in this machine without the attendance of a man, by the following training. — Attach a bell to the lever of draught (h), use eye-binders to prevent the animal from seeing whether or not any one is in attendance, and from becoming giddy by going constantly round. Put the animal in motion, and the bell will not stop ringing till he stops. The moment he stops, and the bell ceases to ring, apply the whip severely. Continue to do this every time the animal stops, till the two hours' labour are completed; then unyoke and feed. After one or two hours, or whatever period may be deemed necessary for rest and refreshment, yoke again, and proceed as before. Go on in this way for two days, and the terror of receiving chastisement when the bell ceases to ring, will have frightened the animal into a habit of working two hours at a time without attendance. This mode is practised successfully in France, Italy, and Spain. (Quere's *Art. Part 4. Book*.)

4500. Pumps are of various kinds, as the lifting-pump, the forcing-pump, for very deep wells the suction pump, and the rotary pump, a recent invention for such as do not exceed thirty-three feet in depth, and of which there are several varieties, but by far the best is that by Sabe. A good pump for mines pits or reservoirs, where the water is not to be raised above twenty-eight or thirty feet, is that of Robert Buchanan, author of *A Treatise on Hoisting by Steam &c.* because this pump will raise drainings of dunghills, the contents of cesspools, privies, &c. or even water thickened by mud, sand, or gravel. — The points in which it differs from the common pump, and by which it excels it, are, that it discharges the water below the piston, and has its valves lying near each other. The advantages of this arrangement are — that the sand or other matter which may be in the water is discharged without injuring the barrel or the piston-leathers — so that, besides avoiding unnecessary wear and waste the power of the pump is preserved, and it is not apt to be diminished or destroyed in moments of extraordinary exertion, as is often the case with the common and chain pumps — that the valves are not confined to any particular dimensions, but may be made capable of discharging every thing that can rise in the suction-pipe without danger of being choked, and that if, upon any occasion, there should happen to be an obstruction in the valves, they are both within the reach of a person's hand, and may be cleared at once, without the dismemberment of any part of the pump. It is a simple and durable pump, and may be made either of metal or wood, at a moderate expense. — Where clear water only is to be raised, A neat (of Hoxton) curvilinear pump is preferable to the common sort. The advantages depend on the curvilinear form of the barrel, which allows, and indeed obliges, the rod, the handle, and the lever on which it works, to be all in one piece. Hence simplicity, cheapness, freedom of action, more water discharged in proportion to the diameter of the barrel, and less frequent repairs. (*Repository of Arts*, Jan. 1821.) Perkins square-barrelled pump is a powerful engine (*London Journal*, &c.); but this and other contrivances for raising water, though promising advantages, cannot often be made available by the improver from their not having come into general use.

4501. *Sabe's rotary pump (fig. 698.) appears to us by far the best of modern improvements on this machine. It is used for drawing, raising, and forcing all fluids and liquids, and may be worked by manual labour, steam, or any other power. By the rotation of a roller (a) having paddles or pistons (b) a vacuum is produced within the barrel (c), and in consequence the water flows up the rising trunk (d) through the space into the barrel, and as the paddles go round they force the water through an opening, which occupies it whenever it may be wanted, and by that means produce a continual stream without an air vessel. It is evident that this pump may, by an ascending tube (e), and a cock on the horizontal spout (f) be used as a suction pump, or a forcing*

Pump at pleasure (*Newton's Journal*, vol. ii, 2d series, p. 90)

4503. An old but ingenious mode of raising water from a well in the upper part of a house (Fig. 699)

is sometimes adopted on the Continent. A post is fixed close to the wall, this is connected with the opening in the upper part of the house, where the water is to be introduced by a fixed cord (a). On this cord a wooden collar (b) is placed, and slides freely from one end to the other: the bucket rope is put through a hole in the collar and over a pulley in the window in the upper part of the house, and thus the bucket is first raised perpendicularly from the water in the well till it comes in contact with the collar, when, the power being continued, the collar slides along the fixed rope till it reaches the operator at the window (Last, Col. de Meckens etc).

4503. *Artificial springs.* Marshal seeing the formation of natural springs, and observing the effect of subsoil drains, and being, at the same time, aware of an objection to roof water which, though more wholesome, is seldom so well tasted as spring water, was led to the idea of forming artificial land springs, to supply farmsteads with water, in dry situations. He proposed arresting the rain-water that has filtered through the soil of a grass ground situated on the upper side of the buildings, in covered drains, clayed and dished at the bottom, and partially filled with pebbles or other open materials thus conveying it into a well or cistern, in the

manner of roof water and by this means uniting, it is probable, the palatableness of spring water with the wholesomeness of that which is collected immediately from the atmosphere.

4504. *Water for common farm-yard and domestic purposes* may be obtained in most situations, by collecting that which falls on the roofs of the farmery and dwelling-house. This is done by a system of gutters and pipes, which, for the farmery, may lead to a cistern or tank under ground and for the family that from the roof of the dwelling-house may be conducted to a tub. According to Wastell, a sufficient supply of water has been collected from the roof of a cottage to answer every purpose of the family during the driest season, by preserving the water so collected in a tank. The quantity of water that falls annually upon every hundred superficial feet, or square of building, is about 1400 gallons. Before using the water so collected, it should be filtered and it seems very desirable that it should undergo this operation before it enters the tank.

4505. *The operation of filtering* may be performed in various ways:—

4505. A very simple mode is by having two casks two or three feet high and of any convenient width (Fig. 700). One of these casks (a) may receive the water from the roof or from any other supply; the other (b) should have a false bottom (c) perforated with holes and covered with flannel: on this flat bottomed equal quantities of sand and charcoal may be laid to the depth of twelve or fourteen inches, and covered with another false bottom similar to the first (d); the remainder of the cask will contain the filtered water which may either be drawn off as wanted by a cock (e), or allowed to pass into an underground tank by the same means. The grosser impurities will always be deposited at the bottom of the filtering tank (b), and these may be drawn off at pleasure by a cock (f), placed immediately above the bottom of the barrel. The sand and charcoal may also be freed from any impurities which they may contract, by first allowing both barrels to be quite full and then turning the bottom cock (g), in consequence of which the filtered water will descend through the filter and clear it. The advantage of having two barrels for the purpose of filtering the water from a roof is partly to retain a larger quantity

the first barrel, from ponds or other sources, in seasons when the roof is unproductive. When the water is to be preserved in a tank under ground, only one barrel (d) is necessary: the pipe from the roof (g) proceeding, in that case, at once to the bottom of the filtering barrel, and entering where, in the case of two barrels, the junction-pipe (h) enters. In all cases of preserving water whether filtered or unfiltered, it is of great importance to preserve a steady and a low temperature, and for this purpose an underground reservoir is highly desirable.

4507. The best form for a tank, according to Wastell, is a circular plan: the bottom in the form of a flat dome covered, and the top also domed, with an opening left in the centre of sufficient size to admit a man to clean it out occasionally. "The top of this opening should be a little above the surface of the ground, and should be covered with an oak dug, with several holes bored in it for ventilation: or the cover may be an iron grating, horizontal, and a little elevated, or conical. These tanks may be constructed of various dimensions: the depth and width should be nearly equal; a hole should also be left for the service-pipe, or that which conveys the water into the tank, and also for the pipe for the pump, if the water be drawn out by that means. The water may be filtered previously to its entering the tank; the hole for the service-pipe ought, therefore, to be near the top, and on that side most convenient for the filtering chamber; this may be about four feet in diameter, and three feet deep: across this, about twelve

Sketches from the side next the tank (fig. 701) a sloped partition from the top to within about six inches from the bottom, should be fixed; at the bottom of the box should be put clean coarse sand or pounded charcoal, about a foot in thickness. The pipe or opening from the filter to the reservoir should be of ample dimensions, and be made at about eighteen or twenty inches from the bottom, in the small division or space behind the shade (b). Above this opening, and in any part most convenient (as) in the large division of the filter, should be an opening or drain to carry off the water when the tank is full. This filter should also have a cover that it may be cleaned out, and fresh sand or other purifiers put in as often as may be found requisite. Of course the water as it comes from the roof is to be first conveyed into the large division of the filtering chamber on the opposite side to the shade partition (b), and passing through the sand it rises in the small division purified, when it is to pass into the tank. If there are two or more of these filtering chambers, or if they are of greater depth, the water may be passed through the greater quantity of sand, &c. in them, and be still more purified. Both the tanks and the filters should be water tight. If constructed of brick, the inner course may be built with Roman cement, and afterwards the whole of the inside covered with a coat of about three quarters of an inch thick. Water from drains formed in the ground for the purpose of collecting it for domestic purposes, may be purified, by passing it through a sand filter previously to its entering the tank or reservoir. Sponge and dannel may also be used as filters. In constructing tanks of the above description care must be taken to have the earth to have the earth closely filled around the brick work, and to allow sufficient time for the work to get properly settled, previously to admitting any great weight of water." (*Agricultural Buildings* p. 15)

4506. Filtering water on a large scale may be effected by emptying one pond into another on a lower level, through a conduit of any kind filled with gravel, sand, and charcoal.

4508. A filtering apparatus for salt water has been invented, but we are unable to say how far it has succeeded. It, at any rate, will succeed well with fresh water and, we have no doubt, to a certain extent also with that of the sea. Fig. 702 is a cylindrical vessel of wood, or any other suitable material which is lined on the inside with cement as far as the filterer extends, it is the bottom of the filterer formed with a grating which is supported by the frame of a stool. c is a pipe extending from the under part of a cask (d) containing the salt water and which pipe opens to the lower part of the vessel a below the filterer. Over the grating (b) there are placed several thicknesses of woven horse hair, or a quantity of wool, and above this the vessel is filled with sand. On the top of the sand there is a plate (e) like a piston pressing upon the sand and keeping it compact, the plate being held down by a screw (f). The salt water thus delivered from the cask (d) by the pipe (c) fills the lower part of the vessel (a) and by the superincumbent best pressure of the column descending from the cask, the water is forced upwards through the mass of sand, and runs off at the cock (g) in a purified state. There are man holes (A, B) for the purpose of getting access to the interior when it is required to remove the sand or other matters and the internal surface of the filterer is rendered rough in order to prevent the water from sliding up the sides of the vessel, instead of passing through the sand. (*Newton's Journal*, vol. i. 54 series p. 188)

4510. The distillation of pale ale water or sea has been effected by P. Nicolle, of Droppie, by simply causing the steam arising from boiling sea water in a still to pass through a stratum of coarsely powdered charcoal, in its way to the condenser or worm-tub. (*Mechanics Magazine*, vol. iv. p. 290.)

4511. Water casters, formed of blue slate, or Yorkshire paving-stones, are much better than those made of wood, and lined with lead. (*Newell's Agricultural Buildings*, p. 15.)

#### CHAP. IV

##### Improvement of Lands lying Waste, so as to fit them for Farm-Culture.

\*4512. Of waste lands, many descriptions are best improved by planting and therefore are to be considered as disposed of in that way in the laying out or arrangement of an estate, but there are others which may be more profitably occupied as farm-lands and it is the preparing or bringing of these into a state of culture, which is the business of the present chapter. Such lands may be classed as mountainous or hilly grounds, rocky or stony surfaces, moors, bogs, or peat-moors, marshes, woody wastes or wealds, warrens or downs, and sea-shores or beaches. In the improvement of these, many of the operations are such as are performed by temporary occupiers or farmers but, as in this case such occupiers have always extraordinary encouragement from the landlords, either in the shape of a low rent, of money advanced, of long leases, or of all of these, we consider it preferable to treat of them as permanent, or fundamental improvements, than to consider them as parts of farm-culture. The delusive prospects of profit, from the improvement of wastes, held out by speculative men, have an unhappy tendency to produce disappointment in rash and sanguine adventurers, and ultimately to discourage such attempts as, with judicious attention to economy, would, in all probability, be attended with great success. Those who are conversant with the publications that have lately appeared on this subject must be aware with what caution the alleged results of most of these writers

ought to be examined; and how different has been the experience of those who have ventured to put their scepticism in practice, from what they had been led to anticipate. (*Gen. Rep. Scot.*)

**SECT. I. Mountains and hilly Grounds and their Improvement.**

4513. The upper parts of mountains may be considered as among the least improvable parts of the earth's surface, from the impossibility of ever ameliorating their climate. "The highest peaks and ridges are mostly naked granite, slate, or volcanic productions. Their more elevated sides, and the tops of those of moderate height, are usually covered by a thin soil, producing a short dry herbage, which is frequently mixed with a dwarf, or stunted heath. Where the soil is not injured by moisture, these are best calculated for sheep. When the height of mountains exceed 800 feet of elevation above the level of the sea, unless covered either with natural woods or artificial plantations, they can only be profitably used in pasture." (*Code.*)

4514. The hills, or lands less elevated than mountains, have, in general, a deeper and moister soil, and produce a more luxuriant herbage, but of a coarse quality hence they are better adapted for small hardy cattle. Though the summits of hills are generally unfit for raising grain, yet the plough is gradually ascending along their sloping sides, and within the last thirty years many thousand acres in such situations have been reclaimed in the United Kingdom.

4515. Sheep lands along the sides of rivers and small streams are often inaccessible to the plough, and unfit for tillage. The more rugged of these are well calculated for woods or coppices; while those in more favourable situations and climates may be converted into orchards. (*Code of Agr. 161*)

**SECT. II. Rocky or Stony Surfaces.**

4516. Rocky and stony lands are common in the valleys of a hilly or mountainous country, and sometimes, as in Aberdeenshire, they cover immense tracts of flat surface.

4517. When rocks protrude from the surface here and there in fragments of a few tons, and it is considered desirable to render the field or scene fit for erection, the only mode is to rend them asunder by gunpowder, and then carry off the fragments for walls, drains, roads, or buildings, or, if they are not wanted for these or any other purpose, to bury them so deep in the ground as to be out of the reach of the plough. But where rocks run in considerable masses of several poles in diameter it will generally be found preferable to enclose and plant them. Clefts and crevices are found in all rocks which have been long exposed to the air and weather and in these may be inserted young plants, or weeds, or both. Such masses being enclosed by rough stone walls, formed from the more detached fragments, or from loose stones, will grow up and be at once highly ornamental and useful as shelter. It is true they will interrupt the progress of the plough in a straight line, but not more so than the rock if left in a state of nature. When a rocky surface is not intended to be ploughed, all that is necessary is to remove as many of the solitary rocks as possible, and either enclose and plant the rest, or cover them with earth.

4518. The stones which impede the improvement of land are either loose, thrown up when the land is trenched, or ploughed or fixed in the earth, and not to be removed without much labour and expense.

4519. Loose stones may often be converted into use for the purpose of forming covered drains, of constructing walls or fences, or of making and repairing the roads on the farm or in the neighbourhood. and, on these accounts, are sometimes worth the trouble of collecting. They may be removed, with the least inconvenience, when the land is sowed. Where loose stones are of a moderate size, they are sometimes found advantageous rather than detrimental, as in the stone-brush walls of Aberdeenshire and other districts. They prevent evaporation, and thus preserve moisture in the soil. Hence the old remark that farmers have been inclined to bring back again to their corn-fields these very stones they have been inclined to carry off. (*Code.*)

4520. Where stones are large and fixed in the earth, if they appear above the surface they should be removed before the ploughing of the waste commences but where they are concealed under the surface, various modes to get rid of them have been adopted. In some parts of Yorkshire, the whole surface is gone over with stump pullers, which, at the distance of every twelve or fourteen fathoms, are thrust into the ground to the depth of about a foot, to ascertain where stones are to be met with. The spot is marked by a twig, and the stones are removed before the land is ploughed. Sometimes the plough is used without such previous examination, and the place marked where stones are encountered, that they may be taken away; and sometimes, in order to discover and remove such stones, the land is trenched by the spade. (*Communications to the Board of Agriculture vol. II. p. 526.*)

4521. Stones along the surface may be avoided by the ploughman, though not without loss of ground; but stones under the surface are often not discovered till the plough is drawn against them, and perhaps broken, by which a day's work is sometimes lost. A wooden belt, however, to unite the horses, leads to the chain of the plough, may prevent mischief by giving way. Clearing the ground from stones not only prevents wind mischief, but is attended with several funds. When removed, they may be used for various purposes, and are often far cheaper than if dug, or purchased at a quarry. The soil round a large stone is barren, in ploughed, the belt in the fall, and is bought at a low rate by the expense of taking out the stone, so the plough has their means to all the land around it. In stony land the plough must proceed slowly and cannot perform half as much work as it ought to do; but, after such impediments have been removed, the field may be ploughed with the usual facility and cheapness, and in a much more perfect manner. It frequently happens, this when waiting heavy land, much expense is incurred in one season by the breaking of the horses, the injury done to the harness and harness, that would cure the soil. (*Gen. Rep. of Scot. vol. II. p. 628; Keesler's Const. Farmer, p. 66.*)

4232. There are various modes of getting rid of stones. These are generally of such a size as to admit of being conveyed away in carts or other vehicles calculated for the purpose. Some ingenious artificers have constructed machines for raising them, when large. On some occasions, pits have been dug close to large stones, and the latter have

been turned into the former as such a depth as to lie out of the reach of the plough; but it is frequently necessary to reduce their size by the force of gunpowder before they can be removed. Loose stones are commonly moved by levers, and rolled on a sledge but sometimes they are raised by a block and tackle attached to a triangle with a pair of calipers to hold the stone (fig 703.) The stone may also

obliquely and then inserting an iron bolt with an eye (fig 704), which, though loose, will yet serve to raise the stone in a perpendicular direction

4233. Richardson's machine for raising large stones (fig 705)

consists of a frame-work supporting a five-fold tackle, with blocks ten inches in diameter and a roller seven inches in diameter turned by two long iron levers. A hole is made in the stone to be raised by means of the tool well known to masons as a *jangger* in this hole a sample plug may be driven tightly or a compound plug (fig 706.) may be introduced or what is simplest, the hole may be made obliquely (*Smith's Compendium of Practical Mechanics*)

4234. The mode of boring or treading rocks or stones by gunpowder is a simple though dangerous operation. When a hole is to be made in a rock for the purpose of blasting with gunpowder the practical workman considers the nature of the rock and the inclination or dip of the strata, if it is not a detached fragment, and from these determines the calibre, and the depth and direction of the bore or rampart for the gunpowder. According to circumstances, the diameter of the hole varies from half an inch to two inches and a half the depth from a few inches to many feet, and the direction varies to all the angles from the perpendicular to the horizontal. The implements for the performance of this operation are rude, and so extremely simple

and familiar as hardly to require description; and the whole operation of boring and blasting rocks is so easily performed, that, in the space of a few weeks, an intelligent labourer may become an expert quarryman. A writer in the *Mechanics Magazine* has proposed to increase the effect of the gunpowder by widening the lower extremity of the bore, and this he thinks may be effected, after the bore is made of the proper length by introducing an instrument with a jointed extremity which would work obliquely

707

4235. The operation of tunnelling frequently gives rise to accidents, but a recent improvement, that of using a wadding of loose sand, or of any earthy matter in a dry state, answers all the purposes of the firmest ramming or wadding. It has been used for upwards of ten years at Lord Knap's extensive mining operations at Charleston in Fife-shire, and also in removing enormous bodies of rock from the Caithness hill at Edinburgh, by Stevenson, an eminent engineer, whose article on the subject of blasting, in the *Days to the People*, well deserves the attention of such as use the process in working quarries or clearing rocky or stony grounds.

4236. Dr Dyer of Aberdeen has communicated to Mr Brewster's Journal an account of a cheap and effectual method of blasting granite rock, which deserves the particular attention of the owners and workers of quarries. It is beautifully simple, and may be summed up under the three following heads: viz. 1. To ignite the gunpowder at the bottom of the charge, by means of sulphuric acid, charcoal, and sulphur. 2. To take advantage of the propelling power

is gunpowder, as is done with a cannon ball, only instead of a spherical ball, to employ one of a conical form (Fig. 703.), by which the full effect of the wedge is given in every direction at the lower part of the charge, but particularly downwards. And, in the last place, to add to the effect of the whole, to insert a fourth part of the depth of the bore of the bottom (b) to be free from the gunpowder, so that, when instantaneous action, a red heat may be communicated to the air in the lower chamber, whereby it will be expanded to such a degree as to have the power of at least one hundred times the atmospheric pressure, and thereby give this additional impulsion to the explosive power of the gunpowder. (*Dr Brewster's Edin. Journ.* Oct. 1836. p. 543, and *Gard. Mag.* vol. II. p. 467.)

4527. The *Armenians* close the mouth of the hole by driving in with a mallet a stout wooden plug some inches in length, through which a touch-hole is bored. Between the powder and the lower part of the plug, an interval of several inches is left. The communication is perfected by means of a tin tube filled with powder, and passing through the centre of the plug. (*Monthly Magazine.*)

### SECT. III. Improving Woody Wastes or Wastes.

4528. With surfaces partially covered with bushes and stumps of trees, ferns, &c., the obvious improvement is to grub them up, and subject the land to cultivation according to its nature.

4529. The growth of large trees is a sign that the soil is naturally fertile. It must also have been enriched by the quantity of leaves which in the course of ages have fallen and rotted upon the surface. Such are the beneficial effects of this process, that after the trees have been cut down, the soil has often been kept under crops of grain for a number of years without interruption or any addition of manure but land thus treated ultimately becomes so much reduced by great exhaustion, that it will not bear a crop worth the expense of seed and labour (*Comm. to the Board of Agr.* vol. II. p. 257.) It is evident, however, that this deterioration entirely proceeds from the improvident management previously adopted. In reclaiming such wastes, the branches of the felled trees, are generally collected and burnt and the ashes, either in whole or in part, are spread on the ground, by which the fertility of the soil is excited. Indeed, where there is no demand for timber on the spot, nor the means of conveyance to any advantageous market, the whole wood is burnt, and the ashes applied as manure.

4530. Much coppice land has been grubbed up in various parts of England, and brought into tillage. Sometimes woods are grubbed for pasture merely. In that case the ground should be as little broken as possible, because the surface of the land, owing to the dead wood and leaves rotting time out of mind upon it, is much better than the mould below. It soon gets into good pasture as grass land, without the sowing of any seed. (*Comm. to the Board of Agr.* vol. IV. p. 45.) But by far the most eligible mode of converting woodland into arable is merely to cut down the trees, and to leave the land in a state of grass until the roots have decayed, putting down with the scythe from time to time any young shoots that may arise. The roots in this way instead of being a source of anxiety and expense, as they generally are, become a source of improvement; and a grassy surface is prepared for the operation of sod burning. (*Moravia's Forthshire*, vol. I. p. 316.)

4531. Natural woods and plantations have been successfully grubbed up in Scotland. In the lower Turfwood in Stirlingshire, many acres of natural coppice were cleared, and the land is now become as valuable as any in the neighbourhood (*Stirlingshire Report*, p. 213.) On the banks of the Clyde and the Avon, coppices have been cut down, and the land, after being drained, cultivated, and manured, has been converted into productive orchards. In Perthshire, also, several thousand acres of plantations have been rooted out, the soil, subjected to the plough converted into good arable land, and profitably employed in tillage. (*Perthshire Report*, p. 289.)

4532. For pulling up or rendering smaller the roots of large trees various machines and contrivances have been invented. Clearing away the earth and splitting with wedges constitute the usual mode but blasting is also, as in the case of rocks and stones, occasionally resorted to.

For this purpose a new instrument, called the *blasting-screw* (Fig. 708.), has been lately applied with considerable success to the rending or splitting of large trees and logs of timber. It consists of a screw (a) an auger (b, c) and charging-piece (d). The screw is wrought into an auger hole bored in the centre of the timber here the charge of powder is inserted, and the orifice of the hole in the log is then shut up or closed with the screw when a match or piece of cord, prepared with saltpetre, is introduced into a small hole (e), left in the screw for this purpose, by which the powder is ignited. The application of this screw to the purposes of blasting is not very obviously necessary because, from what we have seen (4525.), it would appear that the auger-hole, being charged with powder and sand, would answer every purpose. One great objection to the process of blasting applied to the rending of timber is, the irregular and uncertain manner in which the fracture is effected. It may however be necessary in some cases, where a great force of men and implements cannot easily be procured or applied; and certainly it is one of the most effectual modes of tearing their stumps or roots in pieces. (*Eng. Agric. Bril. Art. Mining.*)

4533. Land covered with ferns, broom, and other shrubs, is generally well adapted for cultivation. The ferns, or whins (*Ulex europæus*), will grow in a dense clay soil and when found in a thriving state, every species of grain, roots, and grasses, may be cultivated with advantage. The broom, on the other hand, prefers a dry gravelly, or sandy soil, such as is adapted for the culture of turnips. A large proportion of the arable land, in the richest districts of England and Scotland, was originally covered by these two plants; and vast tracts still remain in that state, which might be profitably brought

under cultivation. For this purpose, the shrubs ought to be cut down, the ground trenched, or the plants rooted out by a strong plough, drawn by four or six horses, and the roots and shrubs (if not wanted for other purposes), burnt in heaps, and the ashes spread equally over the surface. (*Com. to the Board of Agr. vol. II. p. 290.*) In many places, shrubs and brushwood may be sold for more than the expense of rooting them out. When coal is not abundant, and limestone or chalk can be had, the furze should be employed in burning the lime used in carrying on the improvement. (*Oxfordshire Report, p. 222*) It requires constant attention, however, to prevent such plants from again getting possession of the ground, when restored to pasture. This can best be effected, by ploughing up the land occasionally, taking a few crops of potatoes, turneps, or tares in rows, and restoring it to be depastured by sheep. In moist weather, also, the young plants should be pulled up and destroyed. (*Code*.)

4534. *Fern* (*Filix* and *Osmunda*) is a very troublesome weed to extirpate, as, in many soils, it sends down its roots into the under stratum, beyond the reach of the deepest ploughing; but it is a sign of the goodness of any soil where it grows to a large size. June and July are the best seasons for destroying it, the plants are then full of sap, and should be frequently cut. They are not, however, easily subdued, often appearing after a rotation of seven years, including a fallow, and sometimes requiring another rotation, and repeated cutting, before their final disappearance can be effected. Lime in its caustic state is peculiarly hostile to fern at the same time, this weed can hardly be completely eradicated but by frequent cultivation, and by green crops assisted by the hoe. (*Oxfordshire Report, pp. 234. 240.*)

4535. *The heath* (*Erica*) is a hardy plant, palatable and nutritious to sheep and under its protection coarse grasses are often produced. When young, or in flower it may be cut and converted into an inferior species of winter provision for stock but where it can be obtained, it is desirable to have grass in its stead. For this purpose, the land may in some cases be flooded, and in others the heath may be burned, and the land kept free from stock for eighteen months in consequence of either of these modes, many new grasses will spring up from the destruction of the heath, and the enriching quality of the deposit from the water or the ashes. The improvement is very great, more especially if the land be drained, and lime or compost applied. (*Gen. Rep. of Scot. vol. II. p. 359*) But if the land be too soon depastured, the grasses being weak and tender, the sheep or cattle will pull them up with their roots, and will materially injure the pasture. (*Statistical Account of Scotland, vol. IV. p. 465.*) Where it is proposed to cultivate the land for arable crops, the lime applied should be in a finely powdered state, highly caustic, and as equally spread as possible. (*Com. to the B. of Agr. vol. II. p. 264.*) Lime in a caustic state is an excellent top dressing for heath. It is astonishing to see white clover spring up, after lime has been some time applied, on spots where not a green leaf could be detected before.

4536. *Paring and burning* is a speedy and effectual mode of bringing a surface covered with coarse herbage into a state of culture. Some have recommended making a compost of the pared surface, with lime, or building folds or earthen walls of the soda, which, by the action of the atmosphere, become friable and fertile, but these processes are slower and not so effectual as paring and burning. In coarse rough pastures, ant-hills frequently abound, which are effectually destroyed by paring and burning. (*Code*.)

#### SECT. IV. *Moors and their Improvements.*

4537. *Moorlands* are of various descriptions. Sometimes they are in low and mild situations, where the upper soil is thin or scantily supplied with vegetable mould, and where the bottom or under-stratum is impervious and barren these, in general, may be reclaimed with more or less advantage, according to the proximity of manure or markets, and of other means of improvement. Sometimes, on the contrary, they are in situations much elevated above the level of the sea, where the surface is covered with heath and other coarse plants, and frequently encumbered with stones such moors are seldom worth the expense of cultivation, and from their height are only calculated for woods or pasturage.

4538. *Moors not placed in high or bleak situations*, where the surface is close-warded, or covered with plants, and where the subsoil is naturally either not altogether wet, or capable of being made sufficiently dry at a moderate expense, may not only be reclaimed, but can often be highly improved by the common operations of farm culture, by paring and burning, by fallow and liming, or by trenching or deep ploughing.

4539. *Few improvements on different sorts of moory lands have been made in Yorkshire where there are immense tracts of moors.* It is stated in *The Agricultural Report of the North Riding of Yorkshire*, that an improvement was made upon Lockton Moor on a quantity of land of about seventy acres, which would not let for more than 1s per acre before it was enclosed. Of this forty-eight acres were pared and burnt, and sown with rape, except about an acre sown with rye, the produce about sixty quarters. The rye grew very strong, and in height not less than six feet, and was sold with standing, for five gallons the acre. The land was only once ploughed, otherwise the crop of rape would probably have been much better. One hundred and twenty staldons (each sterry two bushels) of lime were ploughed into the

4543. which, the want of more frequent ploughing, was probably not of the service it otherwise might have been. Part of the land was afterwards sown down with oats and grass seeds; the sower of which admitted that it was a moderate crop, the latter a very good one, and had sown produced two loads, 120 stones each, per acre. The seeds sown were eye-grass, rib-grass, white clover, and trefoil; of these, the first sown did best, the others not so well. Potatoes thrived very well; turnips not equal to them. A first-horse has been half sown it, which now, along with five acres more of the same kind of land, is let on lease at thirty pounds per annum. The soil consisted, in general, of heavy peat, upon red gritstone, with a mixture of clay upon limestone; this last is, in some places, at a considerable depth, in others, sufficiently near the surface for lime to be burnt on the premises.

4540. *Finlayson's rid-plough* (§ 2605.) has been found a valuable implement in breaking up heath and moorlands, in Scotland.

#### SECT. V. *Peat Mosses, Bogs, and Morasses, and their Improvement.*

4541. *Mossy and boggy surfaces* occupy a very considerable portion of the British Isles. In Ireland alone there are of flat red bog, capable of being converted to the general purposes of agriculture, 1,576,000 acres; and of peat soil, covering mountains, capable of being improved for pasture, or beneficially applied to the purposes of plantation, 1,335,000 acres, making together nearly three millions of acres. Mossy lands, whether on mountains or plains, are of two kinds: the one black and solid, the other spongy, containing a great quantity of water, with a proportion of fibrous materials.

4542. *Black mosses*, though formerly considered irreclaimable, are now found capable of great melioration. By cultivation, they may be completely changed in their quality and appearance, and, from a peaty, become a soft vegetable earth of great fertility. They may be converted into pasture, or, after being thoroughly drained, thriving plantations may be raised upon them; or, under judicious management, they will produce crops of grain and roots; or, they may be formed into meadow-land of considerable value.

4543. *Flow, flood, or spongy mosses*, abound in various parts of the British Isles. Such mosses are sometimes from ten to twenty feet deep, and even more, but the average may be stated at from four to eight. In high situations, their improvement is attended with so much expense, and the returns are so scanty, that it is advisable to leave them in their original state, but where advantageously situated, it is now proved that they may be profitably converted into arable land, or valuable meadow. If they are not too high above the level of the sea, arable crops may be successfully cultivated. Potatoes, and other green crops, where manure can be obtained, may likewise be raised on them with advantage.

4544. *Peat* is certainly a production of the soil, and its administration to the support of many valuable kinds of plants; but to effect this purpose, it must be reduced to such a state either by the application of fire, or the influence of putrefaction, as may prepare it for their nourishment. In either of these ways, peat may be changed into a soil fit for the production of grass, or herbs, or of roots. The application of a proper quantity of lime, chalk, or marl, prepares it equally well for the production of corn. (Code.)

4545. *The fundamental improvement of all peat soils is drainage*, which alone will in a few years change a boggy to a grassy surface. After being drained, the surface may be covered with earthy materials, peat and humus, fallow, dung, manure, or soil. The celebrated Duke of Bridgewater covered a part of Cheshire with the refuse of coal-pits, a mixture of earths and stones of different qualities and sizes, which were brought in barges out of the interior of a mountain, and, by compressing the surface, enabled it to bear pasturing stock. Its fertility was promoted by the vegetable mould of the moors, which presently rose and mixed with the heavier materials which were spread upon it. (Marsden on Landed Property, p. 44.)

4546. *The heavy grounds of Huntingdonshire* are in some cases improved by applying marl to the surface. Where this substance is mixed with the fine soil, the finer grasses flourish beyond what they do on the fine soil unimproved; and when the mixed soil is ploughed, and sown with any sort of grain, the calcareous earth renders the crops less apt to fall down, the produce is greater, and the grain of better quality than on any other part of the land. (Huntingdonshire Report, p. 501.)

4547. *Covering the surface of peat bogs with earth* has been practised in several parts of Scotland. Clay, sand, gravel, chalk, and on some, two or three inches thick, or more, have been used; and land, originally of no value, has thus been rendered worth from 5*l*. to 2*l*., and even 4*l*. per acre. The horses upon this land now, either so equipped with wooden clags, or the work performed in frosty weather, when the surface of the moss is hard. Coarse obdurate clay (provincially *mo*) is peculiarly calculated for this process; as, when it is blended with peat and some calcareous matter, it contains all the properties of a fertile soil. (Orkneyshire Report, p. 145, note.) This is certainly an expensive method of improving land, unless the substance to be laid upon it is within 200 yards' distance; but where it can properly be done, the moss thus decays rapidly, and after it has been supplied with calcareous earth, it may be cultivated, like other soils, in a rotation of white and green crops. In the neighbourhood of populous towns, where the want of land is high, the covering substance may be conveyed from a greater distance than 200 yards. (Code.)

4548. *Rolling peaty surfaces* has been found to improve them. The greatest defect of peat soils is, that the droughty heavy peat, when sown, and they become too even. The roller is an antidote to that evil, and the expense is the only thing that could be set against the question of this operation. It also tends to destroy those worms, grubs, and insects, which whilst light and heavy land is up to be tilled. The roller for such soils ought not to be heavy, nor of a narrow diameter. If it is weighty and the diameter small, it sinks too much, depresses the pressure felt, which causes the soil near to rise hollow and behind the roller, and thus, instead of consolidating, it tends the soil. A gentle pressure consolidates them, but too much weight has a contrary effect. A roller for moss ought therefore to be formed of wood, the cylinder about four feet diameter, and mounted to be drawn by two or three men. Three small rollers working in one line, (see fig. 264,) have sometimes been so drawn. When horses are employed, they ought to have sharp spindles, if likely to sink. The rollers are useful in preparing, on peaty soils as long as the crops of corn or grass will admit of it, the better, and the more certain is the result.

covered with water, or the soil is extremely wet, they may be drained, as large districts in the fens of Lincolnshire have been, and made highly valuable. The object, in that case, is, by sinkbanks, draining, and other means of improvement, to convert these marshes into pasture or meadow, or even arable lands; and where such improvements cannot be accomplished, the most useful woody aquatics, as willows, osiers, &c., may be grown with advantage.

4553. *Romney marsh* is one of the most extensive and fertile fresh-water marshes in Britain. It contains nearly 24,000 acres besides which Walland marsh and Dings marsh, which are comprised within the walls, contain, the former 12,000, and the latter 6,000 acres. Boys informs us that "the internal regulations of these marshes are committed to the superintendence of expeditors. These are appointed by the Commissioners of Sewers, and are to take care that the repairs of the walls are maintained in due order, and that the costs attending the same be levied on each tenant according to the number of acres occupied by him for which purpose they are to cause assessments to be made out, with the names of the occupiers, and the rateable proportions to be borne by them respectively, and these rates, which must be confirmed by the commissioners, are termed scots; and that when any occupier refuses to pay his scot, the expeditor can obtain a warrant from the commissioners, empowering them to distrain for the same, as for any other tax." These marshes are both appropriated to the purposes of breeding and feeding.

4555. *Salt water marshes* are subject to be overflowed at every spring tide, and at other times, when, from the violence of the wind or the impetuosity of the tide, the water flows beyond its usual limits. Their goodness is in a great measure analogous to the fertility of the adjoining marshes and their extent differs according to the situation. Embankments, as it is remarked in *The Code of Agriculture*, are perhaps the only means by which they can be effectually improved, especially when they are deficient in pasture. However, where pasture abounds, they are in some cases more valuable than arable lands, the pasture operating as a medicine upon diseased cattle.

4561. *Marshes on the Thames.* In *The Agricultural Survey of Kent* it is asserted, that great profit is made by the renters of marshes bordering on the Thames, in the neighbourhood of London, from the grazing of horses, the pasture being deservedly accounted salubrious to that useful animal. Such horses as have been worn down by hard travel, or long afflicted with the farcy, lameness, &c., have frequently been restored to their pristine health and vigour by a few months' run in the marshes, especially on the salt-marsh; but as every piece of marsh land in some measure participates of this saline disposition, so do they all of them possess, in a comparative degree, the virtues above mentioned, and for this reason the Londoners are happy to procure a run for their horses, at 4s. or 5s. per week. Another method practised by the graziers in the vicinity of London is, to purchase sheep or bullocks at Smithfield at a hanging market, which, being turned into the marshes, in the lapse of a few weeks are not only much improved in flesh, but go off at a time when the markets, being less crowded, have considerably advanced in price and thus a twofold gain is made from the traffic. Many of the wealthy butchers of the metropolis are possessed of a tract of this marsh land, and, having from their constant attendance at Smithfield, a perfect knowledge of the rise and fall in the markets, they are consequently enabled to judge with certainty when will be the proper time to buy in their stock, and at what period to dispose of them.

4562. In various districts of the island situated on the borders of the sea, or near the mouths of large rivers, there are many very extensive tracts of this description of land, which by proper drainage and enclosure may be rendered highly valuable and productive. This is particularly the case in Somersetshire and Lancashire. In the former of these counties, vast improvements have, according to Billingsley, as stated in his able *Survey*, been effected by the cutting of ditches, for the purpose of dividing the property and the deepening of the general outlets to discharge the superfluous water. Many thousand acres which were formerly overflowed for months together, and consequently of little or no value, are now become fine grazing and dairy lands.

#### SECT. VII. Downes and other Shore Lands.

4563. *Downes* are those undulating smooth surfaces covered with close and fine turf met with in some districts on the sea-shore; the soil is sometimes sandy, and at other times clay or loam. In inland situations there are also down lands, as in Wiltshire, Lincolnshire, and Yorkshire; in the latter two counties they are called wolds.

4564. *Sandy downes on the sea-shore* are often more valuable in their natural state than after cultivation. In a state of nature they frequently afford good pasture for sheep and rabbits, and at other times produce grasses that may be used as food for cattle, or as litter. But the great object should be to raise plants which contribute to fix these soils, and to prevent them from being drifted by the winds, which often occasion incalculable

mischievous. The most suitable plants for the purpose are, the *Elymus arenarius*, *Juncus acutiflorus*, *Arundo Donax*, *Oenothera spinosa*, *Galium verum*, *Tumulus Petasitis*, and a variety of other creeping-rooted plants and grasses. Of woody plants, the alder is one of the best for resisting the sea breeze, and requires only to be inserted in the sand in large truncheons. Where the sands on sea-shores are mixed with shells, and not very liable to drift, if they can be sheltered by fences or an embankment, and sown with white clover, it will be found both an economical and profitable improvement.

4564. The drift sands of the outer Hebrides have in some places been consolidated and covered with verdure by "square pieces of turf, cut from solid sward, and laid upon the drifting surface, in steep places nearer to each other, and in less inclined places at a greater distance on very rapid declivities the turfs are placed in contiguity. These turfs, although separated by intervals of a foot or so of sand are not liable to be buried, except in very exposed places." (*Quar. Jour. Agr.* vol. i. p. 715.) M. Mackenz, Esq. of Harris, has reclaimed and brought into useful permanent pasture above 500 acres of useless drifting sand, by planting it with *Arundo arenaria* (fig. 710) in 1819. The operation is performed in September by cutting the plants "about two inches below the surface with a small thin-edged spade, with a short handle, which a man can use in his right hand, at the same time taking hold of the grass with his left other person carrying it to the blowing sand, and to be planted in a hole, or rather a cut, made in the sand, about eight or nine inches deep, (and deeper where the sand is very open and much exposed,) by a large narrow pointed spade. A handful of *Arundo arenaria*, or bent grass, was put into each of these cuts, which were about twelve inches distant, more or less, according to the exposure of the situation. When properly fixed in the blowing sand, the roots began to grow and spread under the surface, in the course of a month after planting. This grass is relished by cattle in summer, but it is of greater value, by preserving it on the ground for wintering cattle. It would be injudicious to cut it, because it will stand the winter better than any other grass, and is seldom covered with snow. Neither wind, rain, nor frost will destroy it, but the old grass naturally decays towards the latter end of spring and the beginning of summer as the new crop grows. White and red clover will grow spontaneously among this grass in the course of a few years, provided it is well secured. (*Trans. Highl. Soc.* vol. vi. p. 265.)

4566. Poor sandy soils in inland districts are not unfrequently stocked with rabbits. When the productions of arable lands are high, it is found worth while to break up these warrens and cultivate corn and turneps; but it frequently happens that, taking the requisite outlay of capital, and the expenses and risk into consideration, they do not pay so well as when stocked with rabbits. Such lands are generally well adapted for planting;

ing; but in this, as in every other case where there is a choice, circumstances must direct what line of improvement is to be adopted.

4567. Shores and sea beaches of gravel and shingle, without either soil or vegetation, are perhaps the most unimprovable spots of any; but something may be done with them by burying the roots of the arduous grasses along with a little clay or loamy earth. Of these, the best is the *Arundo arenaria* and *Elymus arenarius* (fig. 711 a), already mentioned and *E. geniculatus* (b) and *sibiricus* (c) would probably succeed equally well. The last grows on the sandy wastes of Siberia, and the preceding is found on the shores of Britain.

## CHAP. V

### Improvement of Lands already in a State of Culture.

4568. A profitable application of many of the practices recommended in the chapters of this and the foregoing Book may be made to many estates which have been long under cultivation. It is certain, indeed, that the majority of those who study our work will have that object more in view than the laying out or improvement of estates *ab origine*. Few are the estates in Britain in which the farm lands do not admit of increased value,

by straightening the shape of fields, adjusting their size, improving the fences, draining the soil, or adding to the water; and how are the fisheries that may not be rendered more commodious. Of this, we shall give a few examples, after we have stated the general principles and modes of proceeding.

*SECT. I. General Principles and Modes of Procedure, in Improving Estates already more or less improved.*

4569. *The groundwork of improvement, on which a practical man may tread with safety and full effect, is an accurate delineation of the existing state, together with a faithful estimate of the present value, of the lands, and other particulars of an estate to be improved. A general map of the appropriated lands, readily exhibiting the several farms and fields as they lie, and showing the existing watercourses, embankments, fences, and buildings, the woodlands, standing waters, moorland, and moory grounds; the known mines and quarries; together with the commonable lands (if any) belonging to the estate, forms a comprehensive and useful subject of study to the practical improver. It is to him, what the map of a country is to a traveller or a sea-chart to a navigator. If an estate is large, a faithful delineation of it will enable him in a few hours to set out with advantage, respecting the connections and dependencies of the whole and its several parts, which, were he deprived of such scientific assistance, as many days, weeks, or months could not furnish. If on the same plan appear the rental value of each field or parcel of land, and the annual produce of each mine, quarry, woodland, and productive water, in its present state, the preparatory information which science is capable of supplying may be considered as complete, and it remains with the artist to study with persevering attention the subject itself, in order to discover the species of improvements of which it is susceptible, and the suitable means of carrying them into effect.*

4570. *The species of improvements incident to landed property are numerous. They may, however be classed under the following heads — the improvement of the outline, and general consolidation of an estate by purchase, sale, or exchange: the improvement of the roads of the mines and minerals of the towns, villages, mills, and manufactories of the waters of the woods and plantations; and of the farmhouses and farm lands. This last subject is the most common, and to it we shall devote the succeeding section. To discuss the other species of improvement, as applied to old estates, would necessarily include so much of what has already passed in review in the foregoing Book, as to be wearisome to the reader.*

*SECT. II. Improvement of Farmhouses and Farm Lands.*

4571. *Farm lands are of more or less value according to the means of occupying them. Arable lands in particular require buildings and other conveniences proportioned to the size of a farm. We frequently see tenants curbed in their operations, and incurring a waste of produce, through the want of sufficient homesteads. On the other hand, we sometimes observe a prodigality of expenditure on farm buildings; thus not only sinking money unnecessarily, but incurring unnecessary expences in subsequent repairs, by extending homesteads beyond the sizes of farms. In some cases, therefore, it will be found necessary to curtail the extent of farm buildings, as large barns, in others to enlarge the yards, and in many to add and re-arrange the whole. The subject therefore may be considered in regard to design and execution, but as we have already quoted fully on laying out new farmhouses, we shall here offer only a few general remarks as to alterations.*

4572. *In improving the plan of a farmery, the given intention is first to be maturely considered, and the several requisites to be carefully ascertained. The given site is next to be delineated, so as to show the existing buildings, yards, roadways, and enclosures and then, by maturely studying the plan alternately with the site itself the improver is to endeavour to trace out the most suitable alterations all the while keeping in view the perfection of arrangement, the situation and value of the existing buildings, and the expences of alteration, reconsidering the subject repeatedly, until the judgment be fully satisfied. It is much easier to plan and erect a new farmstead, than to improve one which is already erected. The former requires science and ingenuity only; the latter good sense and judgment also.*

4573. *In executing improvements on old farmhouses, some difficulty occurs as to the incorporation of new and old materials. If the situation and plan are likely to be of permanent approval, the new construction may be made in the most substantial manner; keeping it in view that the old, which are repaired at the time, may afterwards be wholly removed. But if the supplies and improvements are not to extend further than the duration of a lease, or till, by the expiration of various leases, some general plan of improvement can be determined on, then old materials may be used, or less permanent structures may be erected.*

4574. An example of adding part of a newly-enclosed common-field to a small, gradually enclosed green-  
 712  
 farm (see 315), was given  
 in the following cases:

4575. The farmstead (a) and ancient enclosed fields (b), are separated from the common field by a road, and bounded on the other side by a lake. The soil is a soft black earth on a gravelly subsoil; the surface a gentle slope towards the lake. The farm-house is supposed to be already placed in this ancient part; and the object in view is to unite a large portion of the common field, when enclosed, to each ancient farm, so as to get a fair rent for the lands at the least expense. The soil of this common field is a light poor soil, with nearly a flat surface. The circumstances of the country are favourable to large farms, the climate is dry and the situation such as to require shelter. The number of acres to be enclosed and added to this farm is 1900. These will be most advantageously cultivated in six shifts of, 1, turnips (c); 2, barley (d); 3, artificial grasses (e); 4 and 5, the same (f & g); 6, wheat or oats (h). Each shift is proposed to be separated by a plantation for shelter and no inferior divisions are made. In two of the plantations are field-barns, sheds, &c. where the corn grown on one-half of the arable lands is thrashed by a portable threshing-machine, and the straw consumed by cattle. There are cottages at each of these farms.

labourers to attend to the stock, &c. The ridges in each of the breaks or shifts are supposed to extend their whole length; or they may be ploughed as if the whole break were only one ridge, by which means not a moment is lost in turning at the ends, &c. Hereford or Devon oxen are supposed the best of labour on this farm.

4576. In place of the above rotation, wheat may be added after the second year of artificial grasses, and one shift kept entirely under sainfoin. This sainfoin division must of course be changed every sixth or seventh year. However if a proper mixture of artificial grasses is sown, such as red, white, and yellow clover, rib-grass, burnet, sainfoin, timothy, cocksfoot, rye-grass, and soft-grass, the produce will be superior to that from either sainfoin or lucern alone, on a soil such as this, or even perhaps on any soil. Every agriculturist of observation must be aware that the efforts of annual and biennial plants are powerful for a few years at first, and that they uniformly produce a greater bulk than perennials: the latter seem to compensate for this temporary bulk by a steady durable produce.

4577. The old pasture near the house is supposed to be irrigated from the upper part of the lake, by a cut passing near the house. These pastures are particularly advantageous for early lambs, milch cows, &c. and for stock in general in seasons of great drought.

4578. Correcting the outlines of fields is one of the most obvious sources of amelioration on many, perhaps on most, estates. The advantages of proper sized and shaped enclosures have been fully pointed out, when treating of laying out farm lands, and in altering existing fences the same principles must be steadily kept in view; for though, unless by a total eradication of all the existing fences, every requisite may not be attainable, yet such a number may be gained as amply to compensate for the expense. In altering the shape and size of fields, besides the advantages resulting from the improvement in form, it will generally be found that a number of cultivable acres may be added to the farms in proportion to the crookedness and width of the fences. Better drainage and roads will also be obtained, and where ornament is an object, a park-like appearance may be produced by leaving a single tree as part of what may have stood in the eradicated hedge-rows.

**Fig. 713** is an example of describing the shape and size of fields, we shall refer to a farm of 250 acres, situated in England. (See 711.) In this case, the fields were larger than usual, but the fences were in

many parts from ten to fifteen yards in width, more resembling strips of copse wood than fences, as they contained hazel, dogwood, black and white thorns, wild roses, brambles, and a variety of native shrubs. The lines of these fences were so ill calculated for carrying off the surface-water, that in one half of the fields there were open gutters for the discharge of the water collected in the hedge-row ditches.

4500. In the centre of one field (25), for example, above an acre was rendered waste by the water from other fields (10, 11, and 12), which waste, it is curious to remark, might, if laid over the same acre agreeably to the principles of irrigation, have produced annually at least two loads and a half of good hay in place of actually rendering the produce of this acre unsatisfactory. The water of some fields (as 10, 11, and part of 12) ran in a diagonal direction through another (16) two acres of which might have been irrigated by it to advantage.

4501. In the farm, when altered (fig. 714), the fields are more uniform in shape and size, their sides are parallel, and better adapted for ploughing the lands in straight ridges. All the surface-water is

carried off by the open head-ricks. Access is had to every field by the shortest possible road from the farm. Only two-thirds of the number of gates formerly existed are retained. Sixty acres are reserved which were formerly laid, as mentioned, by enclosures, upon for which seed was sold, and by husbandry means and various means; and an house and vegetable garden is obtained from the old hedge bank on, opened almost in every direction, and is still in pasture at least ten acres. The whole is more open and beautiful; and, from the number of single water courses over the fields, more elegant, and bearing a greater resemblance to a park. A part near the bottom of the farm is in permanent pasture, and the rest (A, B, C, &c.) under a course of fallow wheat, clover, turnips, &c.

4583. *An example of altering the fields and surrounding a farm, we select the case of a meadow-farm, with the stable lands in a southern field state. (Fig. 715.) By an act of disincrustation, these pastured stable lands (a) were exchanged for others adjoining the meadow grounds (Fig. 716 B), and the whole im-*

proved more compact and commodious. This farm, being intersected by a public lane, affords an example in which no private roads are wanted. The size and shape of the fields were improved, and the broad fences reduced as in the preceding case, and attended with the same advantages in an agricultural point of view.

4585. *And though in altering broad farms there are obvious and innumerable advantages to the farmer, yet as partly observed by Lord, pain is not every thing. "The houses on the Hedges of English estates," he says, "were liable to the same objection which is applicable to a great proportion of the estates of England. They are not composed of stone, at least but in a mean degree; they are the most pestiferous of bushes, growing from the stumps of every sort of forest-trees, intermingled with hawthorn, holly, hollyhock, maple, silver willow &c. They are planted on high and dry grounds, and thus are subject to constant decay. They destroy too much probably provided agricul-*

*ture alone were the occupation of life. But as they give great protection, when they thrive, to the game, they become an important object of preservation, inasmuch as every thing must be of consequence which contributes to the game, and has the effect of pointing the game of England, which upon their estate. For this reason, it may confidently be proper to consider of the best way to preserve these bushes of the least expense, in place of substituting more perfect ones in their stead, and should one object negatively to be attended to is the particular improvement of a great and so readily country. Such are Mr. Lenth's ideas on game and hedges.*

4584. *When farms-lands are exposed to high winds, interspersing them with strips or masses of plantation is attended with obviously important advantages. Not only are such lands rendered more congenial to the growth of grass, and corn, and the health of pasturing animals, but the local climate is improved. The fact, that the climate may be thus improved, has, in very many instances, been sufficiently established. It is, indeed, astonishing how much better cattle thrive in fields even but moderately sheltered than they do in an open exposed country. In the breeding of cattle, a sheltered farm, or a sheltered corner in a farm, is a thing much prized; and, in instances where fields are taken by the season for the purpose of fattening, those most sheltered never fail to bring the highest rents, provided the soil is equal to that of the neighbouring fields which are not sheltered by trees. If we enquire into the cause, we shall find, that it does not altogether depend on an early rise of grass, on account of the shelter afforded to the lands by the plantations; but likewise that cattle, which have it in their power in cold seasons, to indulge in the kindly shelter afforded them by the trees, feed better; because their bodies are not pierced by the keen winds of spring and autumn, neither is the tender grass destroyed by the frosty blasts of March and April. (Plant. Nat. p. 181.)*

4585. *The operation of above plantations, in exposed situations, Marshal observes, is not merely that of giving shelter to the animals grazing immediately beneath them; but likewise that of breaking the uniform current of the wind,—disrupting the cooling blast, and throwing them into eddies; thus moderating the air to some distance from them. Living trees communicate a degree of actual warmth to the air which envelopes them. Where there is life there is warmth, not only in animal but in vegetable nature. The severest frost rarely affects the sap of trees. Hence it appears, that trees and shrubs properly disposed, in a bleak situation, tend to improve the lands so exposed, in a twofold way, for the purposes of agriculture; namely, by giving shelter to stock by breaking the currents of winds; and by communicating a degree of warmth or softness to the air in colder weather.*

4586. *The proper disposal of above plantations for this purpose is in lines across the north-easterly winds, and in situations best calculated to break their force. Placed across valleys, daps, or narrow-passes, in bleak exposures, they may be of singular use also on the ridges, as well as on the points, top-lands, of hills.*

402. The matter of adverse production might partially be regulated by the value of the land for improvement uses, and the advantages of the situation for the sale and delivery of timber. In ordinary cases, such fees in fact operate rather more to discourage than to encourage an estate which.

4144. The form of plantations for shelter, however, will not in every case be that of a stripe or belt of uniform width. In hilly, rocky and other situations, different forms will suggest themselves, according to the situation and the objects in view. In rocky abrupt sites (pg. 737) the plantation will consist of a

number of leaves (4, 5 etc) of ferns determined by the number and position, among which some of the most valuable points must be left as guides (4, 5, 6) for use when the student is to be able to select a leaf for abstracting or separating entire leaves. Should be formed as much as possible in straight and parallel lines, in order not to increase the expense of billage by short and irregular turnings. Straight parallel lines, on irregular surfaces, have a more varied appearance at a distance, than curves over so much varied on a flat surface. In the former case, the outline against the sky is varied as much as the surface. In the latter case, the outline is straight and the surface is irregular. In the same time to plant only the most risky and unproductive spots, the farmer may be of the same irregular description and by planting chiefly on the eminences and slopes (see 718.) shelter will be most

Effectually produced, the pasture improved, the land valuable ground rendered productive in crops of timber, and the greatest richness and picturesque beauty conferred on the landscape. There are some examples of this in the hilly districts of Fifehire, there, on many estates where nothing was sought for but profit and shelter, the greatest beauty has been produced, and the picturesque tourist now passes through glades and valleys pastured by well-fed cattle and sheep, enveloped by rocks, thickets, hanging woods, and sometimes rills and lakes. Fifty years ago scarcely a tree was to be seen, and only the most inferior descriptions of New Stock.

**4082.** The species of woody plants best adapted for shelter-  
are the rapid-growing and evergreen trees, as the Scotch  
spruce and such as are at the same time clothed with branches  
and the ground sprays, as the spruce, and the forest of  
all broad-leaved timber in the section in very dense growth.  
Among the deciduous trees, the fast-growing trenchy sorts  
are most desirable, as the larch, birch, poplar which in  
very elevated situations, the birch, mountain ash, and Scotch  
fir, which are all well adapted to the system of shelter-planting.  
To maintain a trenchy leafy screen from the ground up-  
wards, intermediate tree and shrubbery such as, or such as  
grow under the shade and drip of others, as the holly, haw-  
thorn, box, yew, &c. To produce shelter and yet admit  
of light and air, the following may suit the purpose, as they  
do not grow, and are chiefly deciduous sorts.

And, in about an hour afterwards, Marshall observes, the hark will generally be found the most profitable, as shelter, but, being doubtful, it does not in winter when its services are most wanted, afford so much shelter as the common pine. A skiver, to shelter five stock, should be close at the bottom, otherwise it is inferior rather than

hatched, not only the blast requiring additional current, but now being liable to be blown through, and to be lodged in cracks on the forward side, to the annoyance and danger of those that have repaired to it for shelter. A lamp plantation surrounded with spruce fir, and these headed at twelve or fifteen feet high, would afford the required shelter for a length of years. The fir, or pine, thus treated, would be inclined to throw out lateral boughs, and feather to the ground while the larches, in show more advanced state of growth, would, by permitting the winter's winds to pass through the upper parts of the skirts, break the current, and destroy the blast.

1922] In winter *penetralia* the branch, by retaining its leaves in winter especially while it is young, serves a valuable purpose. If the outer margins were kept in a state of decayed wood, and cut alternately and the middle portion allowed to rise as timber trees, the triple purpose of stream plantations might be obtained in its distinct forms, and almost in verminity.

light. In deep-soiled oak districts, which not infrequently want shelter, stress of oak might be managed in a similar way. Elm, or other hardy overgrowth, planted as underwood, in groves of either of the above descriptions, would, if suitable situations were assigned them, send much in this direction.

**Uses.** A full-grown shrub, for the purpose of shelter to pasturing stock. Nearly equal to a depth of 100 ft. and, incidentally, preferable to an open grove of timber trees, besides its additional use as a windbreak. These groves are groves of some kind to perfectly adapt to this purpose. This is the commonest kind of shelter and stock fence, namely, a wide brush or mound of earth, planted with poplar trees. This shrub, incidentally on its own, is a shelter and a guard to

[illegible][illegible]

4656. The seeds of hedge maple, proper for several species, depend entirely on the soil and situation. On a bank of hill soil, in a moist situation, the seeds stand off, and are a good choice. The seeds better kept pressed up as to other a close than from being above the top of the bank. It is a narrow border, even against the winter winds of Wind, sharp. The bank is commonly cleared in high exposed situations, and in places more gentle to the growth of wood, the bank, the soil,

and the soil are the ordinary plants of hedge maple. The seeds are here a quality which recommends them, in situations where they will flourish; they grow freely from seed, or transverse cut in the ground, 1/4 of an inch, to cover the growth of ordinary hedge maple, and the seeds are required. The seeds will (often) deposit with grow in high and dry soil.

4658. On steep slopes, tall mounds are difficult to raise; and there alone walls are not only built at a small expense, but are convenient receptacles for the stones with which the soil is encumbered. But a stone wall, unless it be carried up to an immense height, at a great expense, is useless as a screen and may be said to be dangerous as such, in a bleak exposed situation, for as soon as the drifting snow has reached the top of the wall, on the windward side, it pours over it, and inevitably buries the sheep which may be seeking for shelter on the leeward side. Hence, in a situation where shelter is required, it is necessary that a stone fence should be backed with a screen plantation.

4657. To plant trees for shade may in some cases be requisite for agricultural purposes. Where this is the case, close plantations are seldom desirable, a free circulation of air being necessary to coolness; therefore trees with lofty stems, and large heads pruned to single stems, are preferable the oak, elm, chestnut, and beech, for thick shade, the plane, sycamore, and poplar, for shade of a lighter degree.

4658. An example of sheltering a hill farm by plantation, and at the same time improving the shape and use of fields, shall next be given. No farming subject affords better opportunities of introducing hedges, rows, and strips of planting than hill farms. The one under consideration (fig. 719) is a small estate owned by its owner: it consists of nearly 370 acres and is situated in an elevated, picturesque part of a central English county. The soil is partly a stony loam or chalk, and partly a strong rich soil, much bent on clay. The fields are very irregular bounded by strips of timber and oaks. By the alterations and additions proposed (fig. 720) all the most hilly and distant spots will be kept in permanent pasture; and the exposed and abrupt places, angles, &c. planted chiefly with oaks for oaks, and beech for timber and shelter.

4659. The hill farm is situated, where shelter cannot be given to grass and stock by plantations, small circular inclosures have been adopted for that purpose. The diameter of these circles is from 20 to 25  
4 C 2

set, the height of the wall six or eight feet, and a conical roof is placed on them, and covered with turf; but every hollow of this kind are formed without such. They are called in Friesland *stalls*, and were brought into notice, in 1788, by Captain, now Lord Mordaunt, in his Treatise on Dutch Farming, a work in which you shall have recourse in a subsequent section.

## CHAP. VI.

### Execution of Improvements.

4600. *The mode in which improvements are executed is a point of very considerable importance, and may materially affect their success as well as their expense.* We shall first consider the different modes of execution, and next offer some general cautions to be kept in view in undertaking extensive works.

#### SECT. I. *Different Modes of procuring the Execution of Improvements on Estates.*

4601. *The necessary preliminary to the execution of an improvement, is a calculation of the advantages to arise from it, and an estimate of the expense of carrying it into effect.* If the former, taken in their full extent, do not exceed the latter, the proposed alteration cannot, in a private view, be considered as an improvement. The next point to be ascertained is the practicability, under the given circumstances of a case, of executing the plan under consideration. There are three things essential to the due execution of an improvement. 1st, an undertaker, or a person of skill, leisure, and activity, to direct the undertaking. 2d, men and animals with which to prosecute the work. 3d, money, or other means of answering the required expenditure. A deficiency in any one of these may, by frustrating a well-planned work after its commencement, be the cause not only of its failure, but of time, money, and credit being lost. — Improvements may be executed by the proprietor, either directly gradually, by economical arrangements, or remotely, to a certain extent, by moral and intellectual means.

4602. *To execute improvements directly, all that is necessary is to employ a steward or manager of adequate abilities and integrity and supply him with the requisite plans, men, and money.* This will generally be found the best mode of forming new roads, new plantations, opening new quarries or mineral pits, altering the course of waters, and all such creations or alterations as are not included in the improvement of farm lands.

4603. *To procure the gradual execution of improvements on farm lands, various arrangements may be made with the tenants* for example, by granting long leases letting them find the requisites of improvement, and take the advantages during their terms; by granting shorter leases, with a covenant of remuneration for the remainder of such improvements as they have made, at the time of quitting by granting leases, at a low rent, for the first years of the term, to give the tenants time and ability to improve at their own expense by advancing money to tenants at will, or, which is the same, making allowances of rent for specified improvements, to be executed by them under the inspection and control of the manager they paying interest for the money advanced or allowed; by employing workmen on tenant farms the tenants in like manner paying interest on the money expended. The usual interest, till lately was six per cent.; thus estimating the value of the improvement at sixteen years' purchase.

4604. *The moral and intellectual means of improving farm lands consists, as Marshall has observed, in enlightening the minds of tenants.* Though this mode is but of slow operation, and respects improvements in modes of culture, rather than such as require great outlay; yet it deserves notice in this place, as necessary to second the efforts of the landlord.

4605. *Farmer, as moral and intellectual agents may be divided into reading men, and illiterate beings the first also derive hints for improvement from books; but the second can only if at all, derive benefit from examples.*

4606. *With regard to supplying farmers by books, — agricultural newspapers, magazines, and county surveys, are probably what would be read with most eagerness; and as much work is done in statements of what actually has taken place in different situations, by farmers like themselves, perhaps they are the most likely to excite to emulation. Historical relations of the agriculture of other countries are also generally interesting to agriculturists; and though no great professional benefit is to be derived from them, yet they tend to enlarge and liberalise the mind, and promote a taste for knowledge. Under these circumstances, it may be worthy of consideration whether an agricultural library might not be established in the county's office, or some commodious place, for the use of tenants and all other persons belonging to the estate who chose to read them. It is interesting libraries for the use both of farmers and their servants, or, indeed, of whatever classes to use them, have for some time been established, and extensively used in West Lothian, and they are gradually being adopted in other counties both in Scotland and England. (Scott. Mag. vol. ii. p. 301.)*

4607. *The establishment of schools for the children of the lower class of tenants, and of cottagers of every description, is an efficient and desirable source of moral and intellectual improvement; and considering it is founded by experience and the most competent judges, that the education of the lower classes will tend greatly to their improvement and the benefit of society at large, we are of opinion that, wherever there are not already established, they should be introduced. Writing schools, somewhat in the German manner, both for boys and girls, would also be a spiritual improvement in such districts as are visited by a great number of itinerant pedlars, and gypsies.*

4606. *Examples as stimuli to improvement may be exhibited in various ways* by citing a farm to a tenant of superior energy or from a more improved district; by exhibiting improved implements and operations on one particular farm; by an itinerant ploughman or smith, encouraged by a squire and carpenter, and with some implements, to go round the circle and instruct each tenant on his own farm; and finally and perhaps preferably by inducing every farmer to make a tour into some other district once a year.

4607. *In addition to these modes appropriate as we consider for two different classes of tenants, Marshall suggests the following as calculated to insure a spirit of improvement among all farmers not of sufficient energy and intelligence.* They are to be adopted in various ways, by a proprietor, or by the manager of an estate, who has a knowledge of rural affairs, and who possesses the good will and confidence of the tenantry.

4610. *By personal attention alone much is to be done.* By reviewing an estate, once or twice a year, by conversing with each tenant in looking over his farm, and by duly noticing the instances of good management which rise to the eye, and considering those which are bad, *vanity and fear*, two powerful stimulants of the human mind, will be roused, and emulation be created among the inferior managers, while shame will sorely fail to bring up the more deserving of the inferior ranks. If, after repeated exhortations, an irreclaimable sloven be discharged as such, and his farm given to another, proficiency for his superior qualifications as a husbandman, an alarm will presently be spread over the estate, and soon, but those who deserve to be discharged, will long remain in the field of bad management.

4611. *Now by conversation, well directed, something may be done.* If, instead of, on the one hand, collecting tenants to the audit, as sheep to the shearing, and sending them away as sheep that are shorn or, on the other, providing for them a sumptuous entertainment, and committing them to their fate in a state of intoxication, a repeat suited to their conditions and habits of life were met before them, and after this, the conversation bent towards agriculture, by distributing presents to superior managers, and specifying the particulars of excellence, or which the rewards or acknowledgments were severally bestowed, a spirit of emulation could not fail to arise among the higher classes, while the minds of the lower order of tenants, and of the whole, would be stimulated and improved by the conversation.

4612. *By encouraging leading men in different parts of a large estate, men who are looked up to by ordinary tenants, by holding out these as patterns to the rest, by furnishing them with the means of improving their breeds of stock, by supplying them with superior varieties of crops, and with implements of improved construction, in machine and husbandry, much may be done by tempting good husbandmen, and expert workmen from districts of a huddled nature, but under a better system of cultivation to settle upon an estate.*

4613. *By an experimental farm, to try new breeds of stock, new crops, new implements, new operations, and new plans of management, such as ordinary tenants ought not to attempt, before they have seen them tried.* To this important end, let the demesne lands of a large estate, or a sufficient portion of them, be appropriated to a nursery of improvements, for the use of the estate, to be professedly held out as such, and be constantly open to the tenants, more particularly to the exemplary practitioners, the leading men of the estate, just mentioned, who, alone, can introduce improvements among the lower classes of an ignorant and prejudiced tenantry. It is in vain for a proprietor to attempt it. On the contrary the attempt seldom fails to alarm, disgust, and prevent the growth of spontaneous improvement.

4614. *Under the present plan of demesne farming, the tenants see expensive works going forward, which they know they cannot copy and hear of extraordinary profits, by particular articles, which they are certain cannot be obtained by any regular course of business.* They therefore conclude that the whole is mere deception, to gain a pretext for raising the rents of their farms above their value. Whereas, if the demesne lands were held out, as trial grounds for their immediate benefit, and conducted, as such, in a manner intelligible to them, they would not fail to visit them. Instead of large proprietors attempting to rival the meanness of their tenants, in farming for pecuniary profit, which on a fair calculation, they rarely if ever obtain, let their views in agriculture be professedly and effectually directed toward the pecuniary advantages of their tenants, far from these alone can their own arise, in any degree that is entitled to the attention of men of fortune. Instead of boasting of the price of a bullock, or the produce of a field, let it be the pride of him who possesses an extent of landed property, to speak of the flourishing condition of his estates at large, the number of superior managers that he can count upon them, and the value of the improvements which he has been the happy means of diffusing among them. Leave it to professional men, to yeomanry and the higher class of tenants, to carry on the improvements, and incorporate them with established practices, to prosecute pecuniary agriculture in a superior manner, and set examples to inferior tenantry. This is strictly their province, and their highest and best view in life. It has been through the order of men, chiefly of this kind, that valuable improvements in agriculture have been brought into practice, and rendered of general use.

4615. *The possessor of an extent of territory has higher objects in view, and a more elevated station to fill.* As a superior member of society it may be said, he has still higher views than those of aggrandizing his own income. But how can a man of fortune fill what may well be termed his legitimate station in life, with higher advantage to his country, than by promoting the prosperity of his share of its territory, by rendering not one field, or one farm, but every farm upon it productive? This is, indeed, being faithfully at his post, and it is a good office in society, which is the more incumbent upon him, as no other man on earth can of right perform it, valuable as it is to the public.

## SECT. II. General Cautions on the Subject of executing Improvements.

4616. *No work can be prudently commenced until the plan be fully matured, not in idea only but in diagrams, and in models, if the subject requires them* in order that every bearing and every hinge may be sufficiently foreknown, the site of improvement being reverted to, again and again, with the draught or the model in hand, until the judgment be satisfied and the mind be inspired with confidence. If a proprietor have not yet acquired sufficient judgment within himself, let him consult some one man, or one council of men, in whose knowledge and judgment he can confide, and thus fix a rallying point. Having brought his plan to a degree of maturity, in this private manner, he may then venture to publish it, and endeavour to improve it, by the advice of his friends, and the observations of its enemies.

4617. *If a proprietor wants judgment himself, and a friend to supply it, let him not attempt the more difficult works of improvement.* Yet how often we see, both in public and private life, men engaged in arduous undertakings, embarked on the wide ocean of business, without rudder or compass to guide them, depending on casual information, to help them on their way! They are consequently ever of opinion with the last persons they converse with. Such men's decisions and operations are always wrong: and for

an obvious reason. They assault those who are best able to inform them, first; and receive their last impressions from those who are least capable to give them. Men who have neither judgment in themselves, nor any standard of practice to rally at, are liable to be led astray by the plausible schemes of theorists, the greater part of whom know nothing of the practical part of business, and who, by their calculations, both of expense in the outlay and of profit in the return, deceive both themselves and their friends or employers, whose plans may have sinister designs in view; though we believe the errors of speculative men are in most cases owing to their being endowed with more imagination than judgment.

4618. The execution of the different improvements, of which an estate has been found susceptible being determined on, it is always advisable to begin with one which is obvious, which may be effected with the greatest certainty, which will repay most amply the expense of carrying it into effect, or which leads to other improvements, as embankment, drainage, &c. To attempt a doubtful project, while plans which are obvious and certain remain unexecuted to try experiments before the list of known improvements has been gone through, is seldom to be recommended, though it might sometimes turn out to be right.

4619. *All rural operations are more or less public*, and as it were performed on a stage and spectators fall not to criticize. If an experiment should prove abortive, or a proposed improvement turn out to be false, the ardour of the improver will be liable to be damped, his people to be discontented (as partaking in the discredit), and the expecting public around him to be disappointed. A few misarranges, in the outset, might frustrate the best intentions and the most profitable schemes. But if, by prosecuting plain and certain improvements, a man once gains his own confidence, as well as that of the people about him, he may then venture to explore less beaten paths, and thus he will be able to do with greater caution, and more probability of success, by the experience already gained, this being a further motive for pursuing the line of conduct here suggested.

4620. *All works of improvement should be executed with vigour*. Many falter in the midst of well-planned works, either through the want of foresight or of business-like execution. In consequence, the money already expended lies dead, and the works are injured by the delay. Some works, as embankments and drainages, may be ruined by the slightest neglect or relaxation; and, indeed, as Marshall observes, we see, in every department of the kingdom, these and other works deserted, and left to moulder into nuisances or disreputable eyesores.

4621. *In carrying on a work, execute every thing substantially, and in a workman-like manner*. Too often a false economy leads to the subversion of this principle. To save a few pounds in the first cost, materials of an inferior quality are laid in, or a quantity used insufficient to give the required substance and strength to the work. By either of these imprudences, its duration is abridged; and the eventual loss, by repairs and renewal, may be ten times greater than the sum injudiciously saved in the original erection. Nevertheless, to increase the evil of these ill-judged savings, inferior workmen are employed; or efficient workmen at inferior prices, at which they cannot afford to make good work, nor can a superintendent urge them to make it under such circumstances. Consequently the work is ill performed, its duration is still more abridged, and a further loss is incurred by injudicious saving.

4622. *There are cases in which temporary works only are required*. A lease-tenant, for instance, wants to make an improvement which will last as long as his lease, without caring about its further duration. In such a case, it may be well-judged frugality and advisable "cleverness in business," to work up cheap materials in a cheap way but it seldom can be right in the proprietor of a hereditary estate, whose interest in it may be said to be perpetual, to proceed in the same manner. His best policy is to take favourable opportunities of laying in good materials at moderate prices; to use them when duly seasoned; and to employ good workmen at such prices as cannot furnish an excuse for bad workmanship, and will warrant him to enforce good.

4623. *Accomplish one work before another is commenced*. A work may be considered as accomplished when the chief difficulties are surmounted, and the chief cost expended, and, till this is the case, it cannot be prudent to embark in another. By avoiding embarking, the execution of improvements becomes a present pleasure, as well as a source of future profit; no half-finished works are left as monuments of disgrace to an estate and its owner; no time nor interest of money is lost, every work is brought into action and profit as it is finished; and if, as it frequently will happen with the most prudent calculators, the estimated sum has been exceeded, the time may be taken to let the fund of improvements accumulate, so as to enable it to discharge the arrears, and so furnish, as wanted, the estimated sums requisite for the succeeding work.

# BOOK IV

## MANAGEMENT OF LANDED PROPERTY

4624. *The management of an extensive landed estate, like that of every other great property, is a business both of talent and integrity. In former times, when every proprietor may be said to have cultivated the whole of his agricultural territory, it constituted his whole occupation, when not engaged in war; or required a host of managers, if he was a man of the first rank. On the continent, and especially in Russia and Hungary, where estates are of enormous extent, and wholly farmed by the proprietor, the largest estates, as we have seen (4621), are managed by a court of directors, and an executive department, with a numerous body of superintendant officers, artists, and artisans. A better system is now adopted in this country, in consequence of the creation of professional farmers, who, taking large portions of territory from the owner for a certain number of years at a fixed rent, and on certain stipulations for mutual security, occasion little more trouble to the proprietor, during that period, than receiving payments. Hence it is that the management of estates in Britain, though important, is a more simple business than in any other country.*

4625. *Where there are only tenanted holdings, the business of management is very simple: where there are woodlands, it requires a person to look after that department; and where there are waters, quarries, and mines, a greater number of subordinate officers are requisite. But what often occasions most expense, and at the same time is attended with the least profit, is the management of the abstract rights belonging to an estate, such as manorial rights, quit-rents, and other feudal or antiquated trifles or absurdities, which require courts to be holden, and lawyers and other officers to be called in to assist. The only British author who has digested the business of managing estates into a regular system is Marshall, and we shall follow him in considering this subject — 1st, as to the superintendents on the executive establishment of an estate; and, 2dly, as to the general business of management.*

### CHAP. I

#### *Superintendents, or Executive Establishment of an Estate.*

4626. *Though every man who cannot manage his own estate in all important matters, deserves to lose it, yet, as extensive proprietors generally have their properties situated in different parts of the country and have, besides, public duties to attend to, certain subordinate managers become necessary. In *The Code of Agriculture* it is stated, that no individual having a large estate is equal to the task of managing it, unless he is in the prime of life, dedicates his whole time to the business, and gives up every other occupation. It is there stated to have been found expedient, by the proprietor of an estate of great extent, to nominate two or three commissioners to assist him in its management. Under the superintendence of such commissioners, it is said, the affairs of a great property would be as well conducted as on the best managed small or moderate-sized estates: while the duties of the proprietor would principally be to carry the exercise of true benevolence into effect, which would consist in softening severe decisions, or in granting those marks of approbation and reward which, when bestowed by the proprietor himself, are the most likely to produce beneficial consequences. (*Code &c. App. 58*) Such may be the case on a few estates in the British isles not yet brought into a regular system of improvement, and about to be remodelled, of which a grand example occurs in the immense property of the Marquess of Stafford: but, in the great majority of cases, to each estate a manager of qualifications suited to its extent and duties, and a general receiver and controller in the capital or metropolis (if the proprietor and his banker cannot effect these duties between them) are all that is requisite. We shall first offer a few remarks on the qualifications and duties of managers, and next on the place of business and its requisites.*

#### *SECT. I. Steward or Manager of an Estate, and his Assistants.*

4627. *The head manager of an estate ought unquestionably to be the proprietor himself, or his representative, if a minor or otherwise incompetent. Next to the proprietor is his acting man of business, with proper assistants; together with such professional men as advisers as the circumstances of business may render necessary. A tenanted estate differs widely from other species of property, as giving power and authority over persons as well as things. It has, therefore, a dignity and a set of duties attached to it,*

which are peculiar to itself. A man who receives ten thousand pounds a year from the public funds, for instance, is an insulated being, compared with him who receives the same income from landed property, and who is one of society's best members, provided his affairs are judiciously conducted. On the contrary, if, regardless of the dignity and the duties of his station, he lives but to dissipate his income, leaving the government of his estates and their inhabitants to those whose interest and honour are unconcerned in their welfare, or to those whose best interests lie in their derangement, he becomes at once an enemy to himself, to his family and to the community. As unpardonable it would be in the possessor of a kingdom to be ignorant of state affairs, and unmindful of the Ambassadors who reside about his court; or in the commanding officer of a regiment to be a stranger to his men, a priest to his parishioners, or a shepherd to his flock; so for the possessor of a tenanted estate to be ignorant of territorial concerns, and a stranger to his lands and their occupiers.

4626. Though it be an essential part of the duty of a man of fortune to be intimately acquainted with his own affairs, it does not follow that he should be absorbed in them, and neglect his duties as a superior member of society. In all matters of government and command, subordination is essential to good order and success. A commander in chief does not act as plowman, nor does a naval commander reef his sails, or heave his anchor. Each has his subordinate officers to convey his commands, and men to execute them. But it is essentially necessary that the former should be well acquainted with military the latter with naval affairs. Every heir apparent, therefore, to a large landed property, should be regularly, or at least more or less, bred up in the knowledge of rural affairs, so as to fill with honour and profit the high station he has in view. But if the possessor of an estate has not been fortunately initiated in the knowledge which belongs to his station, the task of acquiring it is far from great.

4629. On a large estate we generally find a resident manager, a land steward, a man who has some knowledge of what is termed country business, and who acts under the control of his employer or of a confidential friend, who is more conversant in rural concerns or perhaps of a law agent, who knows less of them; or such residing steward, especially of a detached estate which lies at some distance from the residence of its proprietor, acts without control. In the last case, if he is a man of judgment, it is fortunate both for the landlord and tenant; but, on the contrary, if such possessory manager wants those requisite qualifications, the consequence becomes mischievous to the lands, their occupiers, their proprietors, and the community.

4630. The requisite acquirements of an acting manager, according to Marshall, are, a knowledge of agriculture, surveying, planting, some knowledge of mechanics, natural history, and skill in accounts. Agriculture is the only firm foundation on which the other required attainments can be securely reposed. It is not more essentially valuable in the superintendence than in the improvement of an estate. It is difficult to become an accurate judge of the value of lands without a practical knowledge of their uses; nor can any man without it properly appreciate the management of occupiers, much less assist them in correcting their errors, and improving their practice.

4631. Land-surveying is a requisite qualification. Not so much, however, for the purpose of measuring and mapping out estates at large, as for checking and correcting the works of professional men, as well as to assist in laying out its lands to advantage.

4632. Planning and the management of woodlands, are acquirements that cannot be dispensed with. Nor should his knowledge and attention be confined to the affairs of the estate entrusted to his care; he ought to have some acquaintance with natural history, chemistry and experimental philosophy to enable him to form just notions on the subject of the subterranean productions which it may contain.

4633. Some knowledge of mechanics, and other sciences that are requisite to the business of an engineer, may be highly useful in promoting the improvements incident to landed property.

4634. A competent knowledge of rural architecture, the doctrine of the strength of materials, and the superintendence of artificers, may be said to be of daily use.

4635. A thorough knowledge of accounts is essentially requisite to the manager of a landed estate.

4636. He should be a man of good character of upright principles, and conciliatory manners; to set an example of good conduct to the tenants and to become their common counsellor and peace-maker in those trifling disputes which never fail to arise among the occupiers of adjoining land; and which too frequently bring on serious quarrels and lawsuits, that end in the ruin not only of themselves, but of the tenants themselves. A proprietor has, therefore, an interest in choosing such disputes in the best, and so men can do this with so much effect as a manager in whom they have a proper confidence, and who possesses a due share of popularity on the estate.

4637. The acting manager requires certain assistants on a large estate especially if it lies in detached and scattered parts. Those in general use are a ground officer and clerk.

4638. A land-revee, woodward, or ground officer, is required on each district or department of a large estate to attend not only to the woods and hedge-timber, but to the state of the fences, gates, buildings, private roads, driftways, and watercourses; also to the stocking of commons (if any), and amusements of every kind; as well as to prevent or detect waste and spend in general, whether by the tenants of the estate, or others, and to report the same to the manager.

4639. The office-clerk, book-keeper, or under steward, is employed to form registers,

make out rentals, &c. and keep the accounts of the estate; as well as to assist the manager in his more active employments; also to act as his substitute in case of sickness, or absence; and to bestow his successor in the event of his death, or other termination of his stewardship.

4640. *A law assistant, solicitor, or attorney, may next be considered as requisite to the good management of a landed estate. For although much is to be done by judicious regulations, and the timely interposition and advice of a resident manager, such are the frailties of human nature, that, in a state of civilised society, and of property legal assistance will sometimes be necessary. The error of country gentlemen consists, not in employing lawyers, but in committing the management of their landed estates to them. The employment of law agents as land stewards, however, is not without some reason. Farmers are not for the most part sufficiently skilled in accounts for taking the charge of a large estate, and such of them as are capable, are commonly men of capital, and would not exchange their situation for the less independent one of a land steward. The division of labour, in the case of large estates, is not without its use, and is recognised in practice. A law agent collects the rents and keeps the accounts, often on a very small salary; and in questions of a practical nature, such as the valuation of new leases, the modes of cropping, &c. he advises with a surveyor or land valuer. After all, however, a well chosen land-steward to reside upon the estate, and to consult, when necessary with a lawyer, must be the best plan, even though his salary be higher than that of the law agent, who commonly acts for several proprietors, does not reside on any of their estates, and very likely as we think, cannot do them justice.*

4641. *In the feudal system, under which every manor court was a court of law, we may perceive the origin of law land-stewards. It is allowed by the best agricultural writers in Europe (Chateaubriant, Thier, Thoun, Mathieu de Donbeale, Sigmondini, Jovallanos, Young, Marshal, Brown, Coventry, &c.), that these men by their rigid adherence to precedent in the clauses of leases, have contributed most materially to retard the progress of agricultural improvement.*

4642. *The land-surveyor is another professional man, whom the superintendent of an estate may want to call in occasionally. Not merely to measure and map the whole or parts of the estate, but to assist in matters of arbitration, and the amicable settlement of disputes or to act himself, as valuer or referee.*

## SECT. II. Land Steward's Place of Business, and what belongs to it.

4643. *A manager's place of business may be considered in regard to its situation, accommodations, and appropriate professional furniture.*

4644. *The situation of the place of business should be under the roof of the proprietor's principal residence round which, and in its neighbourhood, some considerable parts of his estates may be supposed (as they ever ought) to lie. If a large bulk of his property lie at too great a distance for tenants to attend at the principal office, and if on this he has a secondary residence, an inferior office is there required for such detached part. And it may be laid down as a rule, in the management of landed property, Marshal observes, that every distant part of an estate ought to have a place upon it (be it ever so humble) in which its possessor may spend a few days comfortably to diffuse over it a spirit of good order and emulation. He has known the most neglected and almost savage spot, such as are many landed estates in Ireland, reclaimed and put in a train of improvement by this easy method.*

4645. *The accommodations requisite for a principal office are, a commodious business room, a small ante-room; and a safe-keep, or strong room, fire proof, for the more valuable documents.*

4646. *The professional furniture with which an office of this description requires to be supplied are maps, rental-books, books of valuation, register, legal papers, and some others.*

4647. *A general map of the whole estate on a large scale is an obvious requisite and portable separate maps, with accompanying registers and other descriptive particulars, are useful in proportion as improve. Maps may be in contemplation.*

4648. *Books of valuation are essential, especially where there are numerous small holdings on short terms. In these registers are contained the number, name, admeasurement, and estimated value of each field, and of every parcel of land, as well as of each cottage or other building not being part of a farmstead, on the several distinct parts or districts of the estate. The valuations being inserted in columns, as they arise, whether by general surveys, or incidentally handed with the names of their respective values, so that whenever a farm is to be let, these columns may be consulted, and its real value fixed in a surveyor with the greatest exactness.*

4649. *A general register of timber trees, copsewood, and young plantations is particularly wanted where there is much hedge-row timber. Marshal directs to specify in this register the number of timber trees in each wood, grove, hedge-row and area, with the species, number and admeasurement of each tree. He also recommends separate pocket-books, containing the particulars of each division, or of a number of contiguous divisions, for the occasional use of the manager and woodmen.*

4650. *Contracts, agreements, accounts, letters on business, and other documents, should be intelligibly endorsed, dated or numbered, and arranged so as to be easily referred to. A book of abstracts, or bags of papers of greater importance, should be made out to be referred to on ordinary occasions, and likewise*

in action, must relate to the subjects, which require a more exact, regular than a common business.

4652. *Capital documents, such as title deeds, legal decisions, awards of arbitration, conveyances of houses, securities, &c., &c., should be deposited in the most important subjects, should be carefully deposited in the safety-chest or strong room.*

4653. *Particular registers of the tenanted lands, in convenient pocket volumes, with maps on a small scale heading every farm, and according to Marshall, who seems to have looked upon tenants as placed in a state of constant hostility with their landlords, a most desirable description of books both for the manager and his employees. Two opposite pages being appropriated to each farm with its map, the following information should be given:—*

*Name of the farm and its number of acres.  
The name of the tenant and the ensuing rent.  
The tenancy; if on lease, the term of expiring.  
Any extraordinary covenant of the lease.  
The number of cottages let with the farm.  
The number of timber trees growing on it.  
The number of orchard trees growing on it.*

*The eligibility of the place and circumstances of the farm.  
The eligibility of the occupier.  
The eligibility of the present rent.  
The state of the buildings, fences, and gates, roads, and watercourses.  
The state of cultivation, and condition of the live stock.*

4654. *And, among other things, the following, viz. —*

*The repairs which immediately wanted.  
The improvements of which the estate is susceptible.*

*The agreements entered into with the tenant.  
The circumstances connected with him.*

*The instructions delivered to him.  
With a hint as to his personal character, and the number and general character of his family.*

4655. *The trouble of forming an abstract of this kind, or of renewing it when filled, or in order to adapt it to the varying circumstances of the several farms, is inconsiderable, compared with its use, which are not only obvious in theory, but are fully established in practice. On returning to an estate, after twelve months' absence, Marshall has generally found, that, by consulting a register of this sort, and, through its means, making systematic enquiries respecting the incidents that have occurred on the several farms during his absence he, in this summary way and before he entered upon a fresh view, became better acquainted not only with the general interests, but with the more ordinary business, of the estate, than the sitting manager, who had constantly resided upon it, without such a memorandum. This abstract or memorandum, he says, ought not to comprehend tenanted farms only, but should comprise woodlands, quarries, the demesne, &c. in hand as well as the more important improvements going on each of which ought to have its separate file assigned it. To a proprietor or his confidential friend, who only goes over his estate occasionally such an intelligent companion is essentially serviceable. He cannot profitably dissent, nor actily advise with, an sitting manager, or other agent or officer of the estate, until he has consulted an infallible guide. The utility of such a register, while a proprietor is absent from his estate, if he can be said to be so, with such a faithful mirror in his possession, is too obvious to require explanation.*

4656. *Among the instruments necessary for a manager's office, may be included those requisite for surveying, mapping, levelling, measuring timber, and every description of country work, together with boring machines, draught measures, weighing scales, astronomical instruments, models, and such other articles as may be required or rendered useful by particular circumstances.*

4657. *An encyclopaedic library may be considered an essential requisite including works on rural architecture, the prices and measuring of work, and other sustaining matters and one of the best encyclopaedias of universal knowledge. We have already suggested an important use to which such a library might be applied.*

4658. *Such an establishment and place of business as has been described, we agree with Marshall in thinking, many will consider as in some degree superfluous or extravagant. In many cases we admit it would be so but it is impossible to determine what things can be done without, unless a particular case were given. Such a minute register of farms, for example, would be quite ridiculous on an estate in East Lothian, where tenants are of sufficient wealth and respectability of manners to be treated as men and not watched and schooled like those which Marshall seems generally to have in view. As tenants of land become enlightened, they will be very differently treated from what in many places they are at present. As a proof of this, we have only to compare one district of country with another. In East Lothian, Berwickshire, and some other parts of Scotland, the farmers are as intelligent as their landlords, and the transactions which take place between them resemble the transactions which take place between one mercantile man and another. In districts where the tenant has little capital, and where he is sunk in ignorance, he ranks with the labourer, and occupies his farm by a sort of subsistence. It is a pity that the ignorance and seclusion of such men do not admit of their comparing their state with that of others possessing no greater capital, but more knowledge and skill: it is a pity, we say, for the sake of their children, whom they might thus be induced to educate.*

## CHAP. II.

### Duties of Managers of Estates.

4659. *The various duties of the manager, or the proprietor, of a landed estate, may be considered under the heads of general business, business with tenants, and building operations.*

### SECT. I. *General Principles of Business considered relatively to Land-Stewardship.*

4659. *The first and most general principle, in this and every other department of business, is to embrace readily the several matters as they occur; and not to put them off from time to time, until they accumulate, and render the task difficult and irksome.* The only artifice, it may be said, which a man of character can well employ in business is that of endeavouring to render it pleasurable; and, by meeting it cheerfully as it rises, or as it becomes ripe for despatch, this desirable end will generally be attained for, in that state a man not only enters upon it with pleasure himself, but he will generally find his opponent in the same temper of mind. Whereas, through delay, misunderstanding, idle tales, and groundless surmises are liable to intervene, the minds of both to be soured, a distant coolness to take place between them and a barrier to be raised, which, though altogether imaginary, nothing but the mystic wend of the law may be able to remove.

4660. *There are three distinct methods of conducting business.* The first is that in which the parties meet, with fair intentions, to find out the point of equity and there to close. In the second, they enter upon business, guarded with cunning, and armed with trick and artifice, as gamblers draw round a table, to take every advantage, fair or otherwise, which they can effect with impunity. The last method lies in the courts of law and equity.

4661. *A business founded on honourable intentions is the only one in which a man of honour can voluntarily appear.* Here honest men come, as indifferent persons, to arbitrate the matter in reference. In every settlement between man and man, there is a point of equity and right, which all good men are desirous to find, and when men of liberal minds fortunately meet and join in the search, it is seldom difficult to be discovered. Should some little difference of opinion arise, let them call in an umpire to decide between them, or leave the whole to the decision of three capable and disinterested men.

4662. *A man of strict integrity may become entangled in business with a man of lower principles.* In this case, it behoves him to be upon his guard, but still to enter into the negotiation with temper and civility. There is even a politeness in affairs of business which cannot be departed from on any occasion. Interruptions and acrimony frequently arise, especially between men who are of keen sensibility, and who (though possibly honest) are insatiable of their own interests, from mere matter of principle. The mind of either being once soured by neglect, or ruffled by disrespectful behaviour, the smooth path of peaceful negotiation is broken up, a spirit of warfare is roused, and advantages are taken, or attempted, which calm reason would not have suggested. Hence, when men of unequal degree are brought together in business, it is incumbent on the superior to set the example of liberality and civility of demeanour.

4663. *In extreme cases there is no resource but the law; and here the most that an honest man can do is to procure, without loss of time, the best advice and to spare no exertion or useful expense in bringing the dangerous and fermenting business to a speedy conclusion.* Not only is a man a property endangered, while it is tossed on the troubled sea of the law but his time and attention are lost away, and his peace of mind is liable to be broken in upon, thus deranging his ordinary concerns, and disturbing the stream of life. How much legal dispute might be prevented by a timely attention to business!

4664. *In forming connections in business, select the man who has a character to lose.* This principle should be invariably acted on for if a man of established good character be properly treated, and determinately closed in with in case he desert or swerve from the right line of conduct, he will not forfeit his good name by doing a disreputable action, and must therefore come forward to the point of equity and justice.

### SECT. II. *Management of Tenants.*

4665. *The general treatment of tenants and cottagers may be considered as the most important part of every land-steward's occupation.* it includes the mode and conditions of letting lands, and the time and manner of receiving rents. The idea of a landlord or his agents managing his tenants does certainly on the face of it appear an absurdity. The tenant is not more obliged to the landlord than the landlord is to the tenant and therefore both parties being on an equality in point of obligation, the one ought not to require or have the power to manage the other. This power is given, however, by the ignorance of one of the parties, and the existing monopoly in favour of the other, and till these are done away with, by education and political changes, the ignorant part of farmers will always be managed by their landlords.

#### SUBSECT. I. *Proper Treatment of Tenants.*

4666. *On every large hereditary estate, there are established customs and usages, to which the proprietor and the occupiers consider themselves mutually amenable, though no legal contracts may subsist between them.* Even where imperfect leases, or other legal agreements exist, still there is generally much left for custom and usage to determine. Though some of these may be improper, yet they ought to be strictly observed by its superintendent, until better can be placed in their stead; not merely on the score of moral justice, but, in the same observance, to set an example of integrity and good faith to the tenants. If a superintendent imprudently break through a custom or a covenant, what can he say to a tenant who follows his example?

4667. *A manager ought to set an example to the tenants under his care of liberality and kindness.* This is more especially applicable to the case of cottagers and others who rent small holdings. There are numberless small favours which he can bestow upon them without loss, and many with eventual advantage to the estate. A spirited super-

big tenant should be refused nothing that he can reasonably ask; should have favours generously conferred upon him, not merely as a reward for the services which he individually is rendering the estate, but to induce its other tenants to follow his example, and to make known to the whole that their conduct is observed, and distinctions made between good and bad managers.

4668. *Estates, like men, have their good and bad characters.* No skilful farmer who has a capital to lose, will take up his residence on an estate of known bad character. On the contrary, when once an estate has acquired the character of good faith and proper treatment of its tenantry, men of money and spirit will ever be anxious to gain a footing there. Besides, the character of an estate will ever involve that of its possessor and, setting income at naught, it surely behoves a man of property to pay some attention to the character of his estates, for what can well add more to the permanent respectability of a family of rank or fortune, than having its estates occupied by a wealthy and respectable tenantry?

4669. *In a state of civilized society and property, one of the great arts of life is to teach character and interest to go hand in hand, and on ordinary occasions to endeavour to turn every incident, as it fortuitously occurs, to their mutual advantage.* If a tenant of capital and an improving spirit be found upon an estate, give him due encouragement, for the purposes already explained. On the contrary, if another is found to possess refractory habits, to swerve from his engagements, or to injure the lands in his occupation, it is but common prudence to take the first legal and fair opportunity of dismissing him, and supplying his place with another who is better qualified to fill it not more with a view of rescuing his particular farm from further injury, and of making an example of him in terror to others of similar habits, than to preserve and heighten the character of the estate.

4670. *These remarks may be considered as applicable chiefly to small tenants, or such as from ignorance and want of leases may be considered in a state of bondage.* It ought never to be in the power of a landlord to make "an example of a tenant in terror to others;" it is enough if this power be left to the laws. A tenant who rents a farm on certain conditions, and fulfils them, is, in point of obligation, on an equality with his landlord: neither is obliged to the other: and while the one does not require those acts of kindness and liberality which Marshal inculcates, the other is not entitled to that submission and slavish deference so common among tenants at will, and indeed most others in England. It is justly observed by Brown (*Treat. on Rur. Aff.*) that the moral encouragement, or degree of encouragement, given to the tenant for improving the ground put under his occupation, is regulated entirely by the terms or conditions of the lease under which he holds possession. If the conditions be liberal and judicious, and accommodated to the soil and situation of the land thereby demised to the tenant, all that is obligatory upon the proprietor is faithfully discharged. But when matters are otherwise, when the tenant possesses under a short lease, when the covenants or obligations are severe in the first instance and ultimately of little avail towards forwarding improvement, it may reasonably be inferred that the connection is improperly constituted, and that little benefit will thence follow either to the public or to the parties concerned. The proper view of a lease is, that it is merely a mercantile transaction reduced to writing, in which both parties are on an equal footing.

#### SUMMARY. 2. *Business of letting Farms.*

4671 *There are three methods of letting a farm* putting it up to public auction, and taking the highest bidder for a tenant receiving written proposals, and accepting the highest offer; and asking more rent for it than it is worth, haggling with different chaps-men, and closing with him who promises to give the most money, without regard to his eligibility as a tenant. After a variety of obvious remarks, Marshal concludes, that "seeing in every situation, there is at all times a fair rental value, or market price of lands, as of their products, there appears to be only one rational, and eventually profitable, method of letting a farm, and this is, to fix the rent, and choose the tenant. In the choice of a tenant every body knows the requisite qualifications to be, capital, skill, industry, and character. The respective advantages of these qualities are amply developed in *The Treatise on Landed Property*."

#### SUMMARY. 3. *Different Species of Tenancy.*

4672. *The different holdings in use in Britain are at will, from year to year, for a term of years, or for a life or lives.*

4673. *The tenant holding at will, as until the customary notice be given by either party to the other, is without any legal contract, or written agreement; the only tie between the owner and the occupier being the custom of the estate or of the country in which it lies, and the common law of the land. This sort is considered as the oldest holding which dissolves the feudal or copyhold tenure but which is now fast going into decay.*

4674. *Holdings from year to year, under a written agreement, with specified covenants, is a more modern*

usage, and tanning more and more prevalent in some parts of England, and among small tenants, even where leases for a term of years were formerly granted.

4675. *Leases for a term of years, or terms, sixteen, twenty, and, or a greater number of years, certain; but without the power of subletting, unless with the consent of the lessor.*

4676. *Leases for lives; an, one, two, three, or more, without the power of subletting.* In Britain, life leases of this description are now rarely granted. In Wales and Ireland they are still prevalent; the rent being there settled according to the value of the land at the time of letting; as on granting a lease for a term. In the western extremity of England, what are termed life leases are still common; but they are rather pledges for money taken up, or deeds of sale for lives, than leases, for security the whole of the estimated sale value of the land, during the life term, is paid down at the time of purchase, the seller reserving only a quit rent, or annual acknowledgment.

4677. *A lease for a term of years, or for two or more lives, can alone be favourable for the progress of agriculture.* A farmer holding at will, or from year to year may plough, sow, and reap but he will, if a prudent man, be very careful not to make improvements, well knowing that the first effect would be a rise of rent or a notice to quit. Leases for a single life have the great disadvantage of uncertainty in duration, both as to landlord and tenant and though the latter may insure a certain sum on his life for the benefit of his family, yet it were better that he should lay out that money in improving the farm. Leases on lives, renewable, are for all purposes of culture as good as freehold; but they have this disadvantage to a tenant, that they require a considerable part of his capital paid down, and a further draught on his capital on the falling in of any of the lives. Even the first of these payments would embarrass the great majority of professional farmers, and disable them from bestowing proper cultivation on the soil; but to a farmer with a surplus capital no description of lease can be better as he lays out his surplus capital at the market rate of interest, and is, as it were, his own annuitant. To the landlord such leases cannot be advantageous, because, there being fewer who can compete for them, lands let on these conditions do not fetch their full price.

4678. *The fundamental principle on which both the duration and conditions of leases are established is evidently this.*—A agrees to lend to B a certain article for his use for an equivalent in money but such is the nature of this article, that, in order to use it with advantage, B must possess it during a considerable time he, therefore, requires a security from A to that effect, and A on his part requires a security from B that he will return the article at least in as good condition as when it was lent to him. The term of years for which the article is to be lent, and the precautions taken to insure its return without deterioration, are founded on experience, and vary according to the peculiar circumstances of lender and borrower. In general, however, this is obvious, that where the period of lending is not sufficient for profitable use, or the conditions required for ensuring the lender an undeteriorated return of the article unreasonable, the value of the loan or rent will be proportionably diminished. (*Sup. Enc. Brit. art. Agr.*)

4679. *In recurring to what actually exists in the best cultivated districts, we shall quote the excellent observations of an experienced farmer and approved public writer.*—"The general principle which should regulate the connection between landlord and tenant seems to be, that while the farm ought to be restored to the owner at the expiration of the tenant's interest, at least without deterioration, the tenant should be encouraged to render it as productive as possible during his possession. In both of these views, a lease for a term of years is scarcely less necessary for the landlord than for the tenant, and so much is the public interested in this measure, that it has been proposed by intelligent men, to impose a penal tax on the rent of lands held by tenants at will.

4680. *That the value of the property is enhanced by the security which such a lease confers on the tenant will be put beyond all doubt, if the rents of two estates for half a century back are compared; the one occupied by tenants at will, and the other by tenants on leases for a moderate term, and where the soil and situation are nearly alike in every respect.* If the comparison be made between two tracts originally very different in point of value, the advantages of leases will be still more striking while that which is held by tenants at will remains nearly stationary the other is gradually yet essentially improved, under the security of leases, by the tenants' capital, and, in no long period, the latter takes the lead of the former, both in the amount of the revenue which it yields to the proprietor and in the quantity of produce which it furnishes for the general consumption. The higher rents and greater produce of some parts of Scotland than of many of the English counties, where the soil, climate, and markets are much more favourable, must be ascribed to the almost universal practice of holding on leases in the former country in much greater degree than to any of the causes which have been frequently assigned. Less than a century ago, what are now the best cultivated districts of Scotland were very far behind the greater part of England; and, indeed, had made very little progress from the time of the feudal system. It is not fifty years since the farmers of Scotland were in the practice of going to learn of their northern neighbours an art, which was then very imperfectly known in their own country. But in several parts of England there has been little or no improvement since, while the southern counties of Scotland have uniformly advanced; and at present exhibit very generally a happy contrast to their condition in the middle of the last century.

4681. *As respect to farmers themselves, it cannot be necessary to point out the advantages of leases.* It may be true, that, under the security of the honour of an English landlord, tenants at will have been continued in possession from generation to generation, and acquired wealth which he has never like the landholders of some other countries, attempted to wrest from them. But there are few individuals in any rank of life, who continue for a length of time to sacrifice their just claims on the altar of parsimony. Something is almost always expected in return. A portion of revenue in this case is exchanged for power, and that power is directed not only to the habitual degradation of the tenantry, but in the control over them, which the landlord never fails to exert at the election of members of parliament, and on all other political emergencies. No prudent man will ever invest his fortune in the improvement of another person's property unless, from the length of his lease, he has a reasonable prospect of being reimbursed

with profit; and the sterility which holding still necessarily entails is altogether incompatible with that spirit of industry which belongs to an independent and independent mind.

4636. Every man who would use a land as a factory for the production of the soil, must deeply affect the public at large, as well as depress one of the largest and most valuable classes. It is clearly their interest, that corn and other provisions should be supplied in abundance, and the people of England may easily imagine of the extent of losses, as one of the principal causes which check the improvement of their own holdings.

4637. What ought to be the form of a lease can only be determined by a reference to the circumstances of each particular case. Lands naturally rich, or such as have already been brought to a high degree of fertility, requiring no great investment of capital, and returning all or nearly all the necessary outlay within the year, may be advantageously held upon short leases, such as perhaps five years for two, or at most three of the rotations or courses of crops to which the quality of the soil is best adapted. The practice of England on this respect is extremely various, almost every farm, from twenty years down to three, being found in different parts of it. In Scotland, by far the most common period is nineteen years, to which it was formerly the practice, in some places, to add the life of the tenant. In that country even when it is thought expedient to agree for a much longer term, this is still expressed in periods of nineteen years, a sort of systematic cycle, which seems to be no less a favourite with the courts of law than with landlords and farmers. Yet this term is somewhat inconvenient, as it can never correspond with any number of the numerous rotations of such land.

4638. A lease for twenty years, it has been maintained by several writers, is not sufficient to reimburse a tenant for any considerable improvements, and landlords have often been urged to agree to a much longer term, which, it is alleged, would be not less for their own interest than for that of the tenant. This is a question which our limits do not permit us to discuss; but, after viewing it in different lights, we must be the supporters of long leases in different parts of Scotland, we cannot help expressing some doubts of their utility even in so far only as it regards the parties themselves, and we are decidedly of opinion, that a greater produce will be brought to market, from any given extent of land held on successive leases of twenty years, for half a century, than if held on one lease of that duration, whether the term be specified, or indefinite as in the case of a lease for life. As a general mode of tenure, leases for lives seem to us particularly disadvantageous.

4639. The great advantage of a lease are so well known in Scotland, that one of her best agricultural writers, himself a landed proprietor, has suggested a method of conferring on it the character of perpetuity, to such an extent as, he thinks, would give ample security to the tenant for every profitable improvement, without preventing the landlord from resuming possession upon equitable terms, at the expiration of every specified period. But the author of this plan (Lord Kames), in his ancient treatise for the advancement of agriculture, at that time in a very backward state in his native country seems to have overlooked the difficulties that stand in the way of its adoption; and the great advances in the price of produce, and consequently in the rate of rents, since his writing, have long since put an end to the discussion which his proposal excited. For a form of a lease on his plan, the reader may consult Bell's *Treatise on Leases* and the objections to the plan itself are shortly stated in the supplement to the sixth edition of *The Gentleman's Magazine* recently published.

4640. Long leases granted upon condition of paying an advance of rent at the end of a certain number of years have been granted. But covenants of this kind, meant to apply to the circumstances of a distant period, cannot possibly be framed in such a manner as to do equal justice to both parties; and it ought not to be concealed, that, in every case of a very long lease, the chances are rather more unfavourable to the landlord than to the farmer. If the price of produce shall continue to rise as it has done, all very lately for the last forty years, no improvement which a tenant can be expected to execute will compensate the landlord's loss; and if, on the other hand, prices shall decline, the capital of most tenants must be exhausted in a few years, and the lands will necessarily revert to the proprietor as has been the case of late in many instances. Hence a landlord, in agreeing to a long lease can hardly ever assure himself that the obligations on the part of the tenant will be fully discharged throughout its whole term, while the obligations he incurs himself may always be easily incurred. He runs the risk of great loss from a depreciation of money, but can look forward to very little benefit from a depreciation of produce, except for a few years at most. Of this advantage a generous man would seldom avail himself; and, indeed, in most instances, the advantage must be only imaginary, for it would be over-balanced by the deterioration of his property (*Sup. Encyc. Brit. art. Agr.*)

4641. There are various objections made to leases of nineteen or twenty-one years. Some of these are of a fiscal and constitutional nature; such as the independence it gives the tenant, who may become a freeholder and manor under the name of their landlord, &c. A greater objection has arisen from the depreciation of British currency during the last ten years of the eighteenth, and first ten of the nineteenth centuries. Various schemes have been suggested to counteract this evil; but the whole of them are liable to objections, and it may be doubted if it admits of any remedy except a compromise between the parties.

#### SUMMARY. 4. Rent and Covenants of a Lease.

4635. To meet the ends of fixed money rents, and long leases, both to landlords and tenants, the best mode known at present is the old plan of corn rents. This plan was first revived in 1811, by a pamphlet published in Cupar, which attracted considerable attention, and has led to the adoption in various parts of Scotland, of a mixed mode of paying rents, partly in corn or the price of corn, and partly in money. In hilly districts, wool, or the price of wool for an average of years, is sometimes fixed on instead of corn. We shall quote from the same intelligent writer on the duration of leases, his sentiments on corn rents, and subjoin his observations on covenants.

4636. Though the most equitable mode of determining the rent of lands on lease, would be to make it vary and fall with the price of grain, yet a rent paid in corn is liable to serious objections, and can seldom be attended to in a successful manner. It necessarily bears hardest on a tenant when he is least able to discharge it. In very bad seasons, his crop may be so scanty, as scarcely to return and reimburse the expense of cultivation, and the share which he ought to receive himself, as the profits of his capital, as well as the quantity stipulated by the landlord, may not exist at all. Though, in this case, if he pays a money rent, his loss may be considerable, it may be twice or three times greater if the rent is to be paid in corn, or according to the high price of such seasons. In long favourable years, which often come in the variable climate of Britain, a corn rent might, in some instances, absorb nearly the whole five or disposable produce, as it is by no means uncommon to find the gross produce of some good land reduced from twenty to fifty per cent. below its average in particular seasons. And it ought to be considered, in regard to the landlord himself, that his surplus would also be depleted or troubled. At a time when all other classes were suffering from dearth, and when the price of grain was high, he might find it difficult to make his business correspond with the great depression of his property. It is of much importance to both parties, that the amount of the rent should vary as little as possible from any untoward cause, though perhaps in general would be perhaps the most injured by such fluctuations.

459. To obviate these and other objections to a corn rent, and to do equal justice at all times to both landlord and tenant, a plan has been lately suggested for converting the corn into money, adopting for its price, not the price of the year for which the rent is payable, but the average price of a certain number of years. The tenant, according to this plan, may be calculated every year, by counting the first year of the series, and adding a new one; or it may continue the same for a certain number of years, and then be fixed according to a year average. Let us suppose the lease to be for twenty-one years, the average agreed on being seven years, and the first year's rent, that is, the price of so many quarters of corn, will be calculated from the average price of the crop of that year, and of the six years preceding. If it be meant to take a new average for the second and every succeeding year's rent all that is necessary is, to strike off the first of these seven years, adding the year for which the rent is payable, and so on during all the years of the lease. But this labour slight as it is, may be dispensed with, by calculating the rent without variation for the first seven years of the lease according to the average price of the seven years immediately preceding its commencement, and, at the end of this period, fixing a new rent, according to the average price of the seven years just expired, to continue for the next seven years. Thus, in the course of twenty-one years, the rent would be calculated only three times: and for whatever quantity of corn the parties had agreed, the money payments would be equal to the average price of four, seven years of the lease itself and of the seven years preceding it: and the price of the last seven years of the old lease would determine the rent during the first seven years of the new one.

460. The landlord and tenant could not suffer. It has been thought, either from bad seasons, or any change in the value of the currency, should such loss as this be extended to several periods of twenty-one years. The quantity of corn to be taken as rent, is the only point that would require to be settled at the commencement of each of these periods: and though this would no doubt be greater or less, according to the state of the lands at the time, yet it may be expected, that in the twenty-one years preceding, all the tenant's judicious expenditure had been fully replaced. Instead of the twofold difficulty in fixing a rent for a long lease, arising from uncertainty as to the quantity of produce, which must depend on the state of improvement, and still more, perhaps, from the variations in the price of that produce, the latter objection is entirely removed by this plan; and in all cases where land is already brought to a high degree of fertility the question about the quantity of produce may likewise be dispensed with.

461. If the corn-rent plan be applied to leases of nineteen or twenty-one years, the inconvenience resulting from uncertainty as to the amount of rent, as well as other difficulties which must necessarily attend it, would be as great, perhaps, as any advantages which it holds out to either of the parties. If it be said that a rent, determined by a seven years' average, could not suddenly nor materially alter this is at once to admit the utility of the contrivance. The first thing which must strike every practical man is, that corn is not the only produce of a farm, and in most parts of Britain, perhaps not the principal source from which rent is paid. And there is no authentic record of the prices of butcher meat, wool, cheese, butter, and other articles in every country to refer to, as there is of corn. Thus it is not the place to acquire values the price of corn regulates the price of all the other products of land, in a country whose statute books are full of duties, bounties, drawbacks, &c. to any nothing of its internal regulations: but it is sufficiently evident that, if corn does possess this power, its price operates too slowly on that of other products to serve as a just criterion for determining rent on a lease of this duration. Besides, in the progress of agriculture, new species or varieties of the cereals themselves are established even in so short a period as twenty-one years; the price of wheat may be very different from that of the corn specified in the lease. What security for a full rent, for instance, would it give to a landlord, to make the rent payable according to the price of barley, when the tenant might find it more for his interest to cultivate some of the varieties of summer wheat, lately brought from the Continent? or according to the price of a particular variety of oats, when, within a few years, we have seen all the old varieties superseded, throughout extensive districts, by the introduction of new ones, the potatoes, which may not be more permanent than those that preceded it? There can be no uncertainty, indeed, in adopting this plan, for ascertaining the rent of land kept always in tillage: but it would be idle to expect any important benefits from it, during such a lease as we have mentioned.

462. The corn-rent plan, in the case of much longer leases, will no doubt diminish the evils which we think are inseparable from them, but it cannot possibly reach some of the most considerable. Its utmost effect is to secure to the landlord a rent which shall in all time to come be an adequate return, according to the state of the lands and the mode of cultivation known at the date of the lease. But it can make no provision that will apply to the enlargement of the gross produce from the future improvement of the lands themselves, or of the disposable produce from the invention of machinery and other plans for economizing labour. And the objections just stated, in reference to a lease of twenty-one years, evidently apply much more forcibly to one of two or three times that length. Old corn-rents, though much higher at present than old money-rents, are seldom or never so high as the rents that could now be paid on a lease of twenty-one years. But, independently of these considerations, which more immediately bear upon the interests of the parties themselves, one insuperable objection to all such leases is, that they partake too much of the nature of entails, and depart too far from that commercial character which is most favourable to the investment of capital, and consequently to the greatest increase of land production.

463. The most recent opinions on the subject are in favour of a money rent, or of a rent formed partly from the average price of produce, and partly of money but somewhat complicated in its arrangement, and therefore not likely to come into general use. There seems, indeed, no essential reason why rents in agriculture should not be regulated on the same general principle as rents in commerce, and were it not for the extraordinary fluctuation that has taken place in the currency of the country within the last forty years, it is more than probable no such alteration of principle would ever have been thought of. The reader who wishes to enter more at length into this subject, may consult the most recent works on political economy and especially Mr. Colclough's *Principles*. He will also find a paper on the subject, of some practical value, in the *Quarterly Journal of Agriculture* vol. i. p. 202. and vol. ii. p. 126.

464. Mr. M'Colclough, in the second edition of his *Principles of Political Economy*, with reference to corn rents, observes, that the disturbing effects of changes in the value of money are avoided, at the same time that the effects of those which occur in the cost of producing corn are mitigated. This plan, he adds, is, however defective, inasmuch as it obliges the tenant to pay more than the fair value of his farm in scarce years: while, on the other hand, it has the effect of improperly reducing the landlord's rent in years of unusual plenty. A simple device has, however, been hit upon, which has gone far to remove these defects: this consists in fixing a maximum and a minimum price, to be settled in the lease; that the produce to be paid to the landlord shall be converted into money according to the current price of the year: but that, in whatever extent prices may rise above the maximum price fixed in the lease, the landlord shall have no claim for such excess of price. By means of this check, the tenant is prevented from paying any great excess of rent in scarce years. And to prevent, on the other hand, the rent from being improperly reduced in very plentiful years, a minimum price is agreed on by the parties, and it is stipulated that, in whatever extent prices may sink below this limit, the landlord shall be entitled to receive this minimum price for the fixed quantity of produce payable to him. This plan has been introduced into some of the best cultivated districts in the empire, particularly West Lothian and Berwickshire; and the experience of the estates in which it has been adopted shows that it is as effective as can well be desired, for the protection of the just rights of both parties, and for securing the progress of agriculture.

465. The terms of payment of rent differ a little in different districts and countries. Some, in Scotland, are paid either previously to the first crop being reaped, when they are called *fore-rents*; or they are paid

4707. The business of receiving the rents and profits of a landed estate, simple as it may seem, is subject to many, and entitled to no consideration. Indeed, on large properties, on which not more than one or two, but various other profits, are to be received, as cottage rents, fish compositions, coal rents; and, perhaps, oak rents of copyhold lands; the business becomes so complex as to require to be methodized and simplified, in order to enable the receiver facility and despatch. This is generally best effected by arranging

distinct days, or distinct parts of the day, for each receipt, so that the different tenants and suitors may know their hours of attendance.

4703. *The business of holding manor courts depends on whether they are held of right, or merely by custom.* If the copyhold tenure is so far worn out in any manner that there are not two ancient or feudal tenants remaining within it, the court has lost its legal power; it cannot by right take cognisance of crimes, nor enforce emendments. Nevertheless, manorial courts have their uses, in regulating firm roads, driftways, and water-courses, and in preventing encroachments of different lands within a manor and it is generally right to preserve the custom of holding them for these purposes.

4704. *Where copyhold courts remain in force, and where legal farms are to be observed, a law "steward of the manor" is proper to hold them.* It is not necessary, however, that courts of this kind should interfere with the receipt of farm rents or that a business of this nature should in any way clash with the general recoverability of the estate. Employ an attorney to hold courts, as a surveyor to arbitrate disputes, or an engineer to plan works of improvement.

4705. *The propriety of having fixed days for receiving the rents of farms is evident and some consideration is required to determine on the season of the year for holding them, so as not to oblige the farmer to forced sales of his produce.* In England and Ireland, farm rents are generally due at Lady-day and Michaelmas, and in Scotland at Candlemas and Lammas. But the proper times of paying them depend on the marketable produce of an estate, and on the season of the year at which it goes in common course, and with the best advantage, to market. A tenant should never be forced to sell his produce with disadvantage nor when he has received his money for it, ought he to be at a loss for an opportunity of discharging his debt to his landlord. On corn-farm estates, or those whose lands are kept in a state of mixed cultivation, which comprise the great mass of farm lands in this kingdom, Michaelmas may be considered as one of the worst times of the year at which to call upon tenants for their rents. It is at the close (or in the northern provinces, perhaps at the height) of harvest, when the farmers' pockets are drained by extra labour, and when they have not yet had time to thresh out their crops to replenish them nor is the summer's grass at that season yet consumed, nor off-going stock, perhaps, yet ready for market. In Norfolk, Marshal found the end of February, or beginning of March a very fit time to pay the half year's rent due at Michaelmas and June for paying those due at Ladyday. In some districts of the north it used to be the custom not to demand the first half year's rent, till the tenant was a year in his farm, by which means he had the use during his lease of nearly a year's rent in addition to his actual capital. But farmers there being now considered as possessed of more wealth than formerly, the first half year's rent of the lease is paid nine months after possession, and the last half year's rent of the term on or immediately before its expiration.

4706. *The proper days for receiving rents are to be determined by the local circumstances of an estate and the district in which it lies more especially by the fairs of the neighbourhood at that season, and by other stated times at which the tenants are accustomed, in conformity with the practice of the country to receive for their dairy produce or other articles delivered in to dealers; and should be fixed immediately after these days of embursemment.*

4707. *On the subject of arrears, a good deal has been said by Marshal; but it is one of those which may very safely be left to the good sense and discretion of the proprietor or his manager.*

### SECT. III *Keeping and Auditing Accounts.*

4708. *Clearness and brevity constitute the excellence of accounts, and these excellencies are only to be obtained by simplicity of method.* Where lands lie in detached estates so as to require different receivers, a separate account is necessarily required for each receivership, but to preserve this simplicity and clearness, it is necessary that the several sets should be in precisely the same form.

4709. *The groundwork of the accounts peculiar to a landed estate is the rent-roll: from this receiving rentals are to be taken, and with these and the miscellaneous receipts and disbursements incident to the estate, an account current is to be annually made out.*

4710. *In the receiving rental the particulars which a receiver wants to see at one view, when receiving the rents of an estate under judicious management, where rents are regularly received, and where occupiers pay taxes and do ordinary repairs, are few; the name of the farm, the name of the tenant, and the amount of his half year's rent, only are required but upon an estate, on which arrears are suffered to remain, and on which matters of account are liable to take place, a greater number of particulars are necessary, as the name of the farm, of the tenant, his arrears, his half year's rent, any other charge*

against him, may allowance to be made him, and the sum receivable, leaving a blank for the sum received and another for the sum left.

4711. *Accounts current* are required to be delivered annually by the acting manager, who ought generally to be the receiver. If the current receipts and disbursements are numerous, or where extensive improvements are going on, and woods, mines, quarries, &c., in hand, such accounts may be given in monthly, which will show the progress of the several concerns, and simplify the business at the end of the year.

4712. On the best managed estates it is usual, besides the books which have been mentioned, to keep a ledger; opening separate accounts for farm lands, woods, mines, quarries, waters, houses and their appurtenances, public works, &c. and where a proprietor has several detached estates, besides such accounts being kept on each, one master ledger contains accounts for the whole property. This, indeed, is nothing but an obvious application of mercantile book-keeping to territorial property, the advantages of which cannot but be as great in the one case as in the other.

4713. In auditing estate accounts, the rent accounts are to be checked with the arrears of the preceding year the column of rents with the rent-roll, corrected up to the last term of entry in order to comprise the fresh lettings, and the columns of account with the particulars, those of allowances being signed by the respective tenants.

4714. The monthly accounts of receipts and disbursements, as well as the annual payments, are to be compared with vouchers. The receipts are checked by deeds of sale, contracts, and other written agreements, the awards of referees, or the estimates of surveyors, the market prices of produce, &c.; the receiver, in every case, identifying the person from whom each sum was received. Each disbursement requires a direct and sufficient voucher, endorsed and numbered, with a corresponding number affixed to the charge in the account, so that they may be readily compared.

4715. The most essential part of the office of an auditor is that of entering into the merits of each receipt and payment and considering whether the charges correspond with the purposes for which they are made; and whether the several sums received are adequate to the respective matters disposed of, by these means detecting and thenceforward preventing imposition and connivance. This, however, is an office which no one but a proprietor, or other person, who has been conversant with the transactions that have taken place upon the estate, and who has a competent knowledge of rural concerns, can properly perform. It may therefore be right to repeat, that if a proprietor has not yet acquired a competent knowledge of his own territorial concerns, to form an adequate judgment of the different entries in his manager's account, he should call in the assistance of those who are conversant in rural affairs, to enable him to judge of any particular parts that may seem to require it; and should not set his hand to an account which he does not clearly understand, nor authorize another to sign it, who may have less knowledge than himself of its merits.

## BOOK V

### SELECTION, HIRING, AND STOCKING OF FARMS.

4716. FARMS or lands let out to men who cultivate it as a business or profession exist in all highly civilized countries. Sometimes the farmer or tenant pays to the proprietor or landlord a proportion of the produce, determined yearly, or as the crops ripen, and sometimes he pays a fixed quantity of produce, or labour, or money, or part of each of them. In Britain, where farming, as a profession, is carried to a higher degree of perfection than in any other country, the connection between landlord and tenant is regularly defined by particular agreements and general laws; and the latter, on entering on a farm, engages to pay a fixed sum for its use for a certain number of years. The sum is fixed according to the estimated value of the land; but being fixed, and for a certain time, it admits of no abatement in proportion to the quantity or value of the produce, as in the proportional or metapher system, general in most countries (265. and 596.); and hence the necessity of a farmer maturely considering every circumstance connected with a farm before he becomes its tenant. The subjects of consideration form the business of this Book, and naturally divide themselves into such as relate to the farm, to the farmer, and to the landlord. Some of the subjects, being treated of in the preceding Book, will be but slightly noticed, though, as connected with the object of the present, they could not be altogether omitted.

## CHAP. I

*Circumstances of a Farm necessary to be considered by a proposed Tenant.*

4717 *Whoever intends to become a professional or rent-paying farmer will, in searching for a farm, find it necessary to attend to a great variety of considerations. Those of the greatest importance may be included under climate, soil, and subsoil, character of surface, topographical position, extent, buildings, roads, fields, tenure, rent, and outgoings. In The Code of Agriculture, a more valuable collection of facts as to these points is brought together than in any other work, and from it, therefore, we shall select the greater part of the following sections.*

*SECT. I. Climate, in respect to farming Lands.*

4718 *The climate of a farm is one of the circumstances over which human art has less control than over any other and a farmer who has but a temporary interest in his possession may be considered as incapable of exercising any influence over it. He may improve the soil and subsoil by draining and culture and the buildings, roads, and fences by additions and alterations but it is for the landlord to attempt improving the climate by planting, and for a future generation to enjoy the effects.*

4719. *Sufficient attention, it is said in The Code of Agriculture, " is rarely paid by the farmer to the nature of the climate in which his operations are carried on. Unless the system he adopts be calculated for the weather his crops are likely to experience, every exertion will often terminate in disappointment. The system that is proper for warm and dry situations is not suitable for cold and wet ones and in a bleak and backward climate, the nature of the soil ought not only to be attended to, but the utmost care ought to be paid to the early sowing of the earliest varieties of seed. Even the species of stock to be bred or kept on a farm should, in a great measure, be regulated by the climate. Hence, this is a subject which the diligent farmer will invariably study with the greatest solicitude. Climate and soil, Curwen justly remarks, are, above all other considerations, those which the farmer ought constantly to keep in view " (Report to the Worthington Society )*

4720. *In considering the climate of a country the following points are of peculiar importance. — Its general character and the means of its improvement its local heat ; the light it furnishes the quantity of its moisture ; the prevailing winds its position, whether maritime or inland ; the regularity of the seasons the phenomena to which it is liable the productions best suited to it the expenses it may occasion in cultivation , and its suitability for the introduction of exotic plants and animals.*

4721. *The general character of a climate not only depends on position or latitude, but likewise on the elevation of a country above the level of the sea its general aspect the vicinity to mountains, forests, bogs, marshes, lakes and seas the nature of the soil and subsoil, and the power which the former possesses of retaining heat and moisture the direction of the winds the length of time the sun continues above the horizon the difference of temperature between the day and the night, and the extent of dry surface in the neighbourhood. The result of these particulars combined form what may be called the general character of climate. Some of the causes of an unfavourable climate cannot be remedied by any human effort in other cases, art may effect much but that art is generally such as the farmer can seldom undertake, unless with a very long lease. Ambitiousness of this sort, therefore, belongs to the landlord.*

4722. *The importance of heat, as a stimulus to vegetation, cannot be doubted. It is at a certain degree of heat that vegetation commences, and it becomes nearly stationary when the temperature falls below it. There are, comparatively speaking but few plants calculated for very cold countries, and these are seldom valuable whereas, in warm and temperate regions, the variety is great, and their value unquestionable. Indeed, such is the effect of cold that, while the thermometer is below sixty degrees of heat, the strongest plants become torpid, and remain in that state while it continues. Revived by the warmth of spring, and strengthened by the heat of summer they acquire fresh life and vigour and are thus better enabled to withstand the rigours of the succeeding winter.*

4723. *An increased temperature when not carried to excess will augment the quantity of nutritive matter in a plant, or improve the quality of fruit grown under its influence. Thus, English barley, of equal weight, is more valuable than the Scotch, because, from growing in a warmer climate, and enjoying the advantage of a greater quantity of heat and light, it is more fully ripened. It thence acquires more saccharine matter and produces a greater quantity of spirit, or of malt liquor. It is also proved, by the experiments of Sir Humphry Davy that wheat, ripened in a more regular and warmer climate, contains more of that valuable article called gluten, than the same species of grain when raised in England.*

4724. *The average heat of the year is not, however, of so much importance to the growth of plants as the duration and its steadiness at a certain degree, during the season when the grain is ripening. Thus the southern climate of the Continent is great advantages over our variable season, in the production of the more delicate sorts of fruit which in this island, are often injured by the frosts in spring, and seldom ripen in a northern climate, where the greatest summer heat is both westerly and of short duration.*

4725. *The quantity of solar light which a climate furnishes, is likewise an important object of enquiry. Light is essential to increase the proportion of starch or farina ; to complete the formation of oils in plants and to give to fruits their proper colour and flavour. It has also the effect of increasing saccharine matter inasmuch that those sugar-canes which are exposed to the sun have more of that important ingredient than when they grow under shade. Nor ought the observation to be omitted, that darkness and light have effects directly opposite upon vegetables. Darkness favours the length of the growth, by keeping up the pliancy of their parts light consolidates them, and stops growth, by hastening maturity. Hence, in the northernmost regions, plants go through all their stages of growth at a time when the sun no longer quits the horizon and the light, of which they then experience the strengthening effect, hinders them before they have time to lengthen. Their growth is therefore quick, but of short duration. They are robust, but undermated. (African) It has been remarked also, that a soil, not suited*

also, will be more productive in a wet climate than in a dry one. Hence, in the western coast of England, as in Lombardy, where the quantity of rain that falls annually varies from forty to sixty inches, a silicious soil is much more productive than the same species of soil in the eastern districts, where seldom more than from twenty-five to thirty-five inches of rain fall in a year. In wet climates, also, even wheat and beans will require a less abundant and abundant soil than in drier situations. At the same time, meadows wonderfully dry in the most favourable to a great produce of corn; and the blossoms of wheat, in particular, set best if no rain falls in the flowering season.

678. The importance of moisture in vegetation is obvious to every one. Water constitutes a large proportion of every plant, and in the vessels of the food of plants held in solution. Hence, without so essential an ingredient, they must either become stunted in their growth or perish. In dry weather, when vegetation ceases at a stand, no sooner do showers of rain fall, than a rapid growth of every kind of herbage immediately ensues, even on poor dry soils, where otherwise, however well manured, vegetation would make but slow progress.

679. The quantity of rain that falls annually in any country is a very inferior consideration, when compared with that of the general and equable distribution of that quantity throughout the several days and months of the year. A great quantity, at the same time, is rather hurtful than beneficial, whereas those moderate, but regular showers, which regularly fall on a soil calculated to receive them, are real sources of fertility. It is by this that the character of a climate, whether wet or dry is chiefly determined, and the operations of agriculture are principally influenced.

680. The utility of a moist atmosphere, with a slow vegetation, is, in some respects, peculiarly remarkable. Thus, in wet climates, as on the western coast of England, Scotland, and Ireland, crops of grain and potatoes are found to exhaust the soil less than in dry situations. Oats in particular are impoverishing in a greater degree in dry climates, than in moist ones; and in the former should be sown much earlier than in the latter.

681. The disadvantages of a wet climate to a farmer more especially if accompanied with a retentive soil, are very great. It is calculated, that in the richest district in Scotland, the Firth of Forth, there are only about twenty weeks in the year fit for ploughing, whereas in several parts of England they have thirty weeks, and in many cases more, during which this essential operation can be performed. Hence ploughing must be much more expensive in the one case than in the other.

682. The season of the year in which rain abounds is likewise of much importance. An excess is prejudicial in any season, but is peculiarly so in autumn when it often lodges the grain by its violence, or by its long continuance prevents the corn from being properly harvested. The hopes of the husbandman are thus blasted, and the fruits of his toil and industry are frequently diminished, and sometimes entirely lost.

683. Dew has a great effect in furnishing plants with moisture; and, indeed, without their aid, vegetation, in wet and dry climates, could go on. Even in temperate regions dews are beneficial. In Guernsey, on the coast of Normandy the autumnal dews are singularly heavy so much so that, in the middle of a hot day, the dew-drops are not quite exhaled from the grass. From this moisture the after grass receives great benefit. Dr. Hales estimated the quantity of dew that falls in one year at three and a half inches. Dalton, at nearly five inches. In this matter, however, it is not easy to be correct.

684. The prevailing winds have a great influence on the character of a climate, and a powerful effect on vegetation. When they pass over a large expanse of water they are usually of a warmer or higher temperature in winter than those which blow over high lands; more especially if such come from countries covered with snow. Hence the east and north-east winds, which have passed over the coldest regions of Europe, are much colder than the west and south-west winds, which blow over the Atlantic Ocean, and they often occasion blights. The former are comparatively drier, unless when accompanied by those thick mists, called fogs, arising from the copious evaporation of the German Ocean. The latter are loaded with the vapours of the Atlantic, and often, from excess of moisture, are rendered prejudicial. The strength of the prevailing winds, or the violence with which they act, more especially during harvest, ought likewise to be considered. If they are very violent, they are apt to affect the crops, and of course it becomes an object to sink the produce to them; and to form fences, enclosures, and plantations accordingly.

685. A maritime position confers a more equal temperature in a climate. Where a great body of land is exposed to the heating rays of the sun, the air becomes much warmer than it would if resting upon a small body of land, contiguous to, or surrounded by the ocean. On the other hand as the sea always preserves nearly the same temperature, and, except in the most northern regions, is never frozen, it communicates warmth in the cold seasons of the year to the air passing over it, which had been cooled in its passage over continents covered with ice and snow. Hence islands are more temperate than continents. It appears, indeed, that the thermometer has not so great a range on the sea coast, as in the more inland parts of Great Britain, even at an elevation of 400 feet above the level of the sea. Of the influence of proximity to the sea many proofs might be brought forward. It is in consequence of this circumstance, that the city of Moscow which is situated somewhat further south than Edinburgh, experiences winters much more severe. Another effect of a maritime position is, that strong winds which blow from the sea are sometimes accompanied by salt spray or vapour, which is injurious to crops of grain, and the leaves of trees; but when it ceases in moderation, those saline particles, with which the westerly winds are loaded, contribute to the verdure of the fields in pasture.

686. The nature of the inland position is also of much importance. The relative position of the neighbouring hills confers a material difference of climate, exposing some districts to great severity of weather and by protecting others from that disadvantage, greatly promoting their fertility.

687. In many countries the seasons are regular. In others, as in Great Britain they are extremely variable, and often change, in the space of a few hours, from dry to moist, from hot to cold, from clear to cloudy, and from a pleasant serenity to all the violence of a tempest. But such irregularities of climate, however unaccountable, are often favourable to vegetation, and compensated by the advantages they produce. It is not in countries where the seasons of heat and cold, wind and rain, are periodical, or where the greatest regularity of climate takes place, that mankind are the most healthy or vigorous, or the useful commodities of the soil most perfect. Perhaps a succession of climates, as well as of other things, is prejudicial rather than useful. Where a climate is inclement, the air is refined and purified by the frequent storms it engenders; and the disadvantages which originate from that source are often counteracted, or at least considerably mitigated, by judicious management, and persevering exertions.

688. The climate of a country is likewise affected by atmospheric and natural phenomena; by earthquakes, volcanoes, violent thunder storms, lightning, hail storms in summer early frosts, whirlwinds and hurricanes, water-spouts, and by that atmospheric appearance, known under the name of the green twinkle, so frequently to be seen in northern, and sometimes even in southern, regions; but these phenomena, for the most part only occasional, sometimes prevent greater calamities, and, in this country are rarely attended with momentary evils.

689. Frost sets in spring are highly injurious to the blossoms of fruit trees; and autumnal frosts creep along the length of rivers, covering the sea in the winter season and blasting the stems of potatoes a low situation. Winter frosts are ultimately rather favourable to vegetation; and more particularly when it ceases the ground for some time, and gradually melts away.

690. The soil, and the manner of the culture of a country, depend upon its climate, by which the nature of the crops must either be adjusted or retarded. The same species of tree, which, in a temperate climate, will rise to a great height, and grow as an handsome size, in an exposed situation will remain small and stunted. By a favourable climate, also, the most barren spots, which in a cold country

must remain completely waste, in a warm one may be rendered productive. Thus, where the climate is adapted to the culture of the vine, rustic, which in Great Britain, and in colder countries, would in general be of little or no worth, in the southern provinces of France may yield as much in valuable produce as the cultivated land in their neighbourhood. The real excellence of a climate, however, depends on its yielding, in perfection and abundance, the necessaries of life, or those which constitute the principal articles of food for man, and for the domestic animals kept for his use. In this point of view, a meadow is much more productive, and in some respects more valuable, than either a vineyard or a grove of oranges; though the one may be situated in a cold and variable climate, and the other in a country selected both for its regularity and warmth of temperature.

4738. *Even the nature of the articles raised depends upon the climate.* Thus, in many elevated parts, both of England and Scotland, wheat cannot be grown to advantage, and in some of the high-lying districts of the latter, it has never been attempted. In several of the northern counties, it has been found necessary to sow instead of the two-rowed barley the inferior sort called bear or big seed oats, from the hardy quality of the grain, are found to be a more certain and more profitable species of corn than any other while in humid districts peas or beans cannot be safely cultivated, from the pernicious wetness of the autumn. On the whole without great attention to the nature of the climate, no profitable system can be laid down by any compiler of land.

4740. *An inferior climate greatly augments the expense of cultivation.* because a number of horses are required for labour during the short period of the year when the weather will admit of it, which, at other seasons, are a useless burden upon the farm. When to this are joined an uneven surface and an inferior quality of soil, arable land is of little value, and yields but a trifling rent.

4741. *Exotic plants or animals can only be naturalised in climates with success by paying attention to that whence they were brought, and by emulating either to render the one as similar to the other as circumstances will admit of, or to counteract, by judicious management, the deficiencies of the new soil.*

4742. *In order to ascertain the nature of a climate the farmer, in modern times, has many advantages which his predecessors wanted for in vain.* The progress of science has given rise to many new instruments, which ascertain natural phenomena with a considerable degree of accuracy. It may still be proper to study the appearance of the heavens, and not to despise old proverbs which often contain much local truth but the vane now points out the quarters whence the winds blow, with all their variations the barometer effects us in ascertaining the state of the weather that may be expected, the thermometer ascertains the degree of heat the hygrometer the degree of moisture the pluviometer or rain-gauge, the quantity of rain that has fallen during any given period, and, by keeping exact registers of all these particulars, much useful information may be derived. The influence of different degrees of temperature and humidity occurring at different times, may likewise be observed, by comparing the leafing, flowering, and after-progress of the most common sorts of trees and plants, in different seasons, with the period when the several crops of grain are sown and reaped each year.

## SECT. II Soil in respect to farming Lands.

4743. *The necessity of paying attention to the nature and quality of the soil need not be dwelt upon.* By ascertaining the qualities it possesses, or by removing its defects, the profits of a farmer may be greatly increased. He must, in general, regulate his measures accordingly in regard to the rent he is to offer the capital he is to lay out the stock he is to keep the crops he is to raise and the improvements he is to execute. Indeed, such is the importance of the soil, and the necessity of adapting his systems to its peculiar properties, that no general system of cultivation can be laid down, unless all the circumstances regarding the nature and situation of the soil and subsoil be known and such is the force of habit, that it rarely happens that a farmer who has been long accustomed to one species of soil will be equally successful in the management of another. From inattention to the nature of soils, many foolish, fruitless, and expensive attempts have been made to introduce different kinds of plants, not at all suited to them, and manures have often been improperly applied. This ignorance has likewise prevented many from employing the means of improvement, though the expense was trifling, and within their reach. From ignorance also of the means calculated for the proper cultivation of the different soils, many unsuccessful and pernicious practices have been adopted. Soils may be considered under the following general heads — Sandy gravelly, clayey stoney chalky; peaty alluvial and loamy, or that species of artificial soil into which the others are generally brought by the effects of manure, and of earthy applications, in the course of long cultivation.

4744. *Though sandy soils are not naturally valuable, yet being easily cultivated, and well calculated for sheep, that most profitable species of stock, they are often favoured with considerable advantage and when of a good quality and under a regular course of husbandry they are invaluable.* They are easily worked, and at all seasons they are cultivated at a moderate expense are not so liable to injury from the vicissitudes of the weather and in general they are deep and retentive of moisture, which secures excellent crops even in the driest summers. The crops raised on sandy soils are numerous, such as turnips, potatoes, carrots, barley, rye, buck-wheat, peas, clover, sainfoin, and other grasses. This species of soil, in general, has not strength enough for the production of Swedish turneps, beans, wheat, flax, or hemp, in any degree of perfection, without much improvement in its texture, the addition of great quantities of enriching manure, and the most skilful management. In Norfolk and Suffolk it is found, that poor sandy soils, unfit for any other purposes, will under suitable produce, after the first year about two tons per acre of excellent hay for several years with an after grass, extremely valuable for rearing and keeping lambs. How much more beneficial than any crops of grain that such soils usually yield! (Young's Improved 150.)

4745. *The fertility of sandy soils is in proportion to the quantity of rain that falls, combined with the frequency of its recurrence.* As a proof of this, in the rainy climate of Turin, the most fertile soil has from seventy seven to eighty per cent. of siliceous earth, and from nine to fourteen of calcareous; whereas in the neighbourhood of Paris, where there is much less rain, the siliceous is only in the proportion of from twenty-six to fifty per cent. in the most fertile parts.

4746. *Gravelly soils differ materially from sandy both in their texture and modes of management.* They are frequently composed of small soft stones, sometimes of flinty ones; but they often contain granite, limestone, and other rocky substances, partially but not very infinitely decomposed. Gravel, being more porous than even sand, is generally a poor and what is called, a hungry soil, more especially when the parts of which it consists are hard in substance, and rounded in form. Gravelly soils are much exhausted; for the mineral and vegetable matters they contain, not being thoroughly incorporated with the stony component parts of the soil (which are seldom sufficiently abundant for that purpose), are more liable to be decomposed by the action of the atmosphere and carried off by water.

6707. *A generally soft, fine from stagnant water, gives such an additional warmth to the climate, that vegetation is thereby a fortnight earlier than where other soils predominate. About Dorchester and Blandford, in Dorset, such soils produce early-green peas, winter turn, rye, autumnal peas, and occasionally wheat, in good condition.*

6708. *Generally soft, in a wet climate, answer well for potatoes; in Cornwall, in a sheltered situation, with a detriment of the wind, and of sea-weed, they raise five crops of potatoes in the same year.*

6709. *Poor generally soft soil of springs, and those sulphureous, are very unfriendly to vegetation; and are better calculated for wood than for arable culture.*

6710. *The heavy clay, or stone-brush soils of Gloucestershire, and the midland counties of England, are much mixed with small stones, but have more frequently sand, or clay or calcareous loam, in their composition than generally soft soils, and are therefore generally preferable.*

6711. *A clayey soil is often of so adhesive a nature that it will hold water like a dish. In a dry summer the plough turns it up in great clods, scarcely to be broken or separated by the heaviest roller. It requires, therefore, much labour to put it in a state fit for producing either corn or grass, and it can only be cultivated when in a particular state, and in favourable weather. Though it will yield great crops under a proper system of management, yet, being cultivated at a heavy expense, requiring stronger instruments and shorter horses, it is seldom that much profit is obtained, unless when occupied by a judicious and attentive farmer. The best management of clay soils is that of the Lothians. There they are found well calculated for growing crops of beans, wheat, oats, clover, and winter turn; but are not adapted for barley, unless immediately after a fallow; nor for potatoes, unless under very peculiar management. In regard to turnips, they do not usually thrive so well in clay, as in soils which are more from sand and open, but it is now ascertained, that the Swedish, and above all the yellow, turnip may be raised in them with advantage; that the quality is superior that if they are taken up early the soil is not injured, and that there is no difficulty in preserving them. Clays become good meadow lands, and answer well for hay or soiling, when in grass; but from their aptitude to be parched, they are, in general, unfit to be fed by heavy cattle in wet weather. In dry seasons the after-grass may be used to feed meat cattle till October and sheep till March. A stiff clay, when not sold or wet, with a strong marl under it, is preferred in Cheshire and Derbyshire for the dairy.*

6712. *On reclaimed peat-lands, oats, rye, beans, potatoes, turnips, carrots, cole-seed, and white and red clover, may be cultivated. Wheat and barley have succeeded on such lands, after they have been supplied with abundance of calcareous earth; and the forin grass (*Agrostis stolonifera*) seems likewise to be well adapted to that description of soil in a warm soil. In Leicestershire, and other counties, there are great tracts of unimproved land; these are, in many instances, the sites of lakes filled up, and the soil is composed of peat and sediment, the peat originally formed by aquatic vegetation, and the sediment brought down by rains and streams from the upland. This soil is admirably calculated for grass.*

6713. *The fens in Cambridgeshire, Lincolnshire, and several other districts in England, consist of peat and sediment.*

6714. *Chalky soils principally consist of calcareous matter mixed with various substances, in greater or less proportions. Where clayey or earthy substances are to be found in such soils in considerable quantities, the composition is heavy and productive; where sand or gravel abounds, it is light, and rather unfruitful. The crops chiefly cultivated on chalky soils are peas, turnips, barley, clover and wheat; and, however much the soil is exhausted, it will produce again.*

6715. *Chalky soils are in general better for tillage than for grazing; for, without the plough, the peculiar advantage derived from the soil by artificial culture could not be obtained. The plough, however, might not be suited to those fine chalky downs (called ewe leas in Dorsetshire), which by a very attentive management during a number of years, have been brought to a considerable degree of fertility as grazing land, and which are so useful to sheep in the winter season. A chalky soil that has been in tillage permits water to pass through it so freely in winter, and is so pervious to the sun's rays in summer, that it is the work of an eye to make it a poor pasture of natural grasses, more especially when the chalk lies near the surface. Hence, in the western counties of England, several thousands of acres of this soil, though not ploughed for thirty years, have scarcely any grass of tolerable quality upon them, and are literally worth nothing. Such soils ought to be laid down with marion.*

6716. *Alluvial soils are of two sorts: one derived from the sediment of fresh and the other from that of salt water. Along the sides of rivers, and other considerable streams, water-formed soils are to be met with, consisting of the decomposed matter of decayed vegetables, with the sediment of streams. They are in general deep and fertile, and not apt to be injured by rain, as they usually lie on a bed of open gravel. They are commonly employed as meadows, from the hazard of crops of grain being injured or carried off by floods.*

6717. *Alluvial soils, arising from the operations of salt water, called salt marshes in England, curves in Scotland, and polders in Holland and Flanders, are composed of the finest parts of natural clay washed off by running water, and deposited on flat ground, on the shores of estuaries, where they are formed by the reflux of the tide, and enriched with marine productions. They generally have a rich level surface, and being deep in the staple, they are well adapted for the culture of the most valuable crops. Hence wheat, barley, oats, and clover are all of them productive on this species of soil; which is likewise peculiarly well calculated for beans, as the tap-root pushes vigorously through it, and finds its nourishment at a great depth. From the great mass of excellent soil, the fertility of these tracts is nearly inexhaustible; but, from their low and damp situation, they are not easily managed. Lime, in considerable quantities, is found to answer well upon this species of soil.*

6718. *The term heavy soil is applied to such as are moderately cohesive, less tenacious than clay and more so than sand. Loams are the most desirable of all soils to occupy. They are friable; can in general be cultivated at almost any season of the year; are ploughed with greater facility, and less strength than clay; bear better the vicissitudes of the seasons; and seldom require any change in the rotation adopted. Above all, they are peculiarly well adapted for the convertible husbandry; for they can be changed, not only without injury, but generally with benefit, from grass to tillage, and from tillage to grass.*

6719. *As to the comparative value of soil, it has been justly remarked, that too much can hardly be paid for a good soil, and that even a low rent will not make a poor one profitable. The labour of cultivating a rich and a poor soil is nearly the same, while the latter requires more manure, and consequently is more expensive. Poor soils, at the same time, may have such a command of lasting manures, as lime or marl, or even of temporary ones, like sea-weed, or the refuse of flax, as may render them profitable to cultivate. It is a wise maxim in husbandry, that the soil, like the cattle by which it is cultivated, should always be kept up in good condition, and never suffered to fall below the work it may be expected to perform.*

### SECT. III. Subsoil relatively to the Choice of a Farm.

6720. *On the nature of the under-structure, depends much of the value of the surface soil. On various accounts its properties merit particular attention. By examining the*

subsoil, information may be obtained in regard to the soil itself; for the materials of the latter are often similar to those which enter largely into the composition of the former though the substances in the soil are necessarily altered, by various mixtures, in the course of cultivation. The subsoil may be of use to the soil, by supplying its deficiencies and correcting its defects. The hazard and expense of cultivating the surface are often considerably augmented by defects in the under-stratum, but which, in some cases, may be remedied. Disorders in the roots of plants are generally owing to a wet or noxious subsoil. Subsoils are retentive or porous.

4761. *Retentive subsoils* consist of clay or marl, or of stone beds of various kinds. A retentive clayey subsoil is in general found to be highly injurious. The surface soil is soaked with water, is ploughed with difficulty and is usually in a bad condition for the exertion of its vegetative powers, until the cold spring moisture of the winter be exhaled. By the water being retained in the upper soil, the putrefactive process is interrupted, and manures are restrained from operating, consequently the plants make but little progress. Hence, its grain is of inferior quality and when in grass its herbage is coarse.

4762. *A stony subsoil*, when in a position approaching to the horizontal, is in general prejudicial, and, if the surface soil be thin, usually occasions barrenness, unless the rock should be limestone; and then the soil, though thin, can easily be converted into healthy pastures, and, in favourable seasons, will feed a heavy stock. They will also produce good crops of corn, though subject to the wire-worm.

4763. *A porous subsoil* is uniformly attended with this advantage, that by its spongy appearance moisture may be absorbed. Below clay and all the variety of loams an open subsoil is particularly desirable. It is favourable to all the operations of husbandry: it tends to correct the imperfections of too great a degree of absorbent power in the soil above. It promotes the beneficial effects of manures: it contributes to the preservation and growth of the seeds; and ensures the future prosperity of the plants. Hence it is, that a thinner soil, with a favourable subsoil, will produce better crops than a more fertile one incumbent on wet clay or on cold and non-absorbent rock. Lands whose substratum consists of clean gravel or sand can bear little sun, owing to their not having the capacity of retaining moisture, and thus generally possessing only a shallow surface of vegetable mould. In England this soil was formerly called *rye land*, being more generally sown with that species of grain than any other. When such soils are cultivated for barley they should be sown early and thick, with seed soaked forty-eight hours in water or in the exudation from a dung-heap. Thus its simultaneous germination and its simultaneous ripening may be secured.

#### SECT. IV. Elevation of Lands relatively to Farming

4764. *The elevation of lands above the level of the sea* has a material influence on the kind and quality of their produce. Land in the same parallel of latitude, other circumstances being nearly similar, is always more valuable in proportion to the comparative lowness of its situation.

4765. *In the higher districts* the herbage is less succulent and nourishing, and the reproduction slower when the land is in grass: while the grain is less plump, runs more to straw, is less perfectly ripened, and the harvest is also later when the produce is corn. It has been calculated that in Great Britain sixty yards of elevation in the land are equal to a degree of latitude: or, in other words, that sixty yards perpendicularly higher, are, in respect of climate, equal to a degree more to the north. In considering the crops to be raised in any particular farm attention ought therefore to be paid to its height above the level of the sea, as well as to its latitude. In latitude  $54^{\circ}$  and  $55^{\circ}$ , an elevation of 500 feet above that level is the greatest height at which wheat can be cultivated with any probable chance of profit, and even there the grain will prove very light, and will often be a month later in ripening than if sown at the foot of the hills.

4766. *The utmost maximum of elevation* may be reckoned between 600 and 800 feet for the more common sorts of grain; and in backward seasons the produce will be of small value and sometimes will yield nothing but straw. It is proper at the same time, to remark that in the second class of mountains in the county of Wicklow in Ireland, where no other grain is considered to be a safe crop, rye is cultivated with success. Where the soil is calcareous however as on the Gloucestershire and Yorkshire wolds, from the superior warmth of that species of soil, compared to cold clays or peat, barley grows in great perfection at an elevation of 800 feet above the level of the sea. Some experiments have been made to raise corn crops, at even a higher elevation, on the celebrated mountain Skiddaw in Cumberland, but unsuccessfully.

4767. *The greatest height at which corn will grow* in the more remote parts of Scotland, so as to yield any profit to the husbandman, is stated to be at 500 feet above the level of the sea. At the same time corn has been produced, in other districts of that country at still higher elevations, in particular at the following places:—

Foot above the Level of the Sea.		Foot above the Level of the Sea.	
Parish of Hume, in Roxburghshire	610	Doulichy in Breemar, Aberdeenshire	1304
Upper Ward of Lanarkshire	760	Lead-hills, in Lanarkshire	1264

4768. *These and other instances of land* being cultivated on high elevations, however, are merely small spots, richly manured, and, after all, producing nothing but crops of inferior barley and oats, and seldom fully ripe or successfully harvested. It is chiefly where the soil is sandy or gravelly that corn will succeed in Scotland on such elevated situations; and even then, only when the seasons are propitious, and when there are local advantages, favourable to warmth and shelter in the situation of the lands.

#### SECT. V. Character of Surface in regard to farming Lands.

4769. *A hilly irregular surface*, whether at a high or low elevation above the sea, is unfavourable to farming. The labour of ploughing, carrying home produce, and carrying out manure, is greatly increased; while the soil on the summit of steep hills, meadows, or declivities, is unavoidably deteriorated. On the sides of slopes the finer parts of the clay and mould are washed away, while the sand and gravel remain. Hence the soil in such

districts often want a proper degree of tenacity for supporting corn crops. A great part of the manure that is applied in such situations is likewise soon lost. From violent rains, also, they are colder than the plains.

4770. *Many extensive countries have no perceptible rise.* These have their advantages from uniformity of soil, where it is rich. In other districts, the surface is of a waving description, an inequality which contributes much to the ornament of the country, by the agreeable relief which the eye constantly meets with in the change of objects; while the universal declivity which prevails more or less in every field is favourable to the culture of the land, by allowing a ready descent to any water with which the surface may be encumbered.

#### SECT. VI. Aspect in regard to farming Lands.

4771. *Aspect, in hilly or mountainous districts,* is an important subject of attention to the farmer; more especially where the climate is unfavourable. It is proved in a variety of instances, both in the central highlands of Scotland, and in other parts of the king dom, that where the aspect of a hill is towards the north, the soil is more fertile than when it lies with a southern exposure. This is attributed to the variations from frost to thaw in the spring months, which are greater in a southern than in a northern aspect. Hence, while the soil to the north remains locked fast, and secured from waste, the other is loosened by the sun, and carried off by showers falling in the intervals of thaw.

4772. *Soils which face the south* are more liable to have their substance carried away by heavy rains, which are generally impelled from the south and south-west. But though the soil to the north often produces the heaviest crops of grass and hay yet from possessing a more genial climate, and from the earlier and more powerful action of the sun, both corn and grass are harvested earlier on land which has a southern than on that which has a northern aspect and superiority of quality thus compensates for any inferiority in the quantity of the produce.

#### SECT. VII Situation of Farm Lands in regard to Markets.

4773. *No farming can go on without markets.* The system of farming to be adopted on any particular farm, and the expense attending it, must materially depend on its situation in regard to markets, to the facility with which its produce can be conveyed, where a contiguous market is wanting, to vicinity to manure, to fuel, and to water.

4774. *The advantages resulting from vicinity to a market,* or to a large town, by which that is insured, are very great. Some crops, as those of potatoes, turnips, and clover are frequently sold on the ground, without any further trouble or expense to the farmer, and great quantities of manure may be purchased at a moderate expense. In such situations also there is a ready sale for every article the farm can produce and the articles sold are not only brought to market at a small expense, but the payment is immediate. For all these reasons, it is contended, and apparently with justice, that the neighbourhood of a market is the most profitable spot to farm in, notwithstanding the high rent of land, and the great expense of labour.

4775. *Where markets are not at hand,* the farmer ought to take into consideration what articles will best suit those at a distance to which his produce must be sent. In such a situation, unless there are facilities for the conveyance of so bulky an article as corn by good roads, or by water-carriage, it is advisable, instead of cultivating grain, to attend either to the dairy husbandry or to the breeding of stock which can be detained in other districts where good markets are more numerous. This plan by which the dairy the breeding, and the fattening of stock, are made distinct professions, is highly beneficial to the economy at large. Stock can be reared cheaper in remote districts than where land is dear and labour high. On the other hand, the purchaser of lean stock avoids the expense and risk of breeding great numbers of animals. His attention is not distracted by a multiplicity of objects, he can alter his system from cattle to sheep, or from sheep to cattle, as is likely to be most profitable, his business is simplified, and the capital he lays out is speedily returned. The division of professions between breeding and feeding (though they may be united in circumstances peculiarly favourable), is on the whole a most important link in the progress of agricultural prosperity.

4776. *In regard to facility of conveyance,* the state of public roads, bridges, turnpike roads, rivers rendered navigable, and harbours, deserves the consideration of the farmer and will most materially influence the value of produce.

4777. *The situation of the farm in regard to manures,* for an easy access to lime, chalk, marl, sea-weed, &c. is of essential advantage to cultivation. The price at which these articles can be purchased, their quality, their distance, and expense of conveyance, are likewise of importance. For instance, procuring the advantage of sea-weed carted up and in abundance, can pay from fifteen to twenty per cent. more rent per acre than otherwise could be afforded.

4778. *Vicinity to fuel* is in the cold and moist regions of Europe an important consideration to the farmer. In the same country, even in England, the difference of expense is often material. In the Highlands, from the moisture of the climate, the expense of fuel is reckoned equal to a third part of the rent of the land; and farmers who pay, in some cases, 100s. per annum, would give 50s. if the landlord would supply them and their servants with fuel.

4779. *Where a farmer is under the necessity of using peat,* from the labour attending the cutting, spreading, drying, and conveying it from a distance, several weeks of his horses and servants are devoted to that sole purpose; and much valuable time is lost, which ought to have been employed in the cultivation of his farm. It has been well remarked, that many farmers, to save five guineas on coal, often expend twenty in thus misapplying the labour of their horses.

4780. *Where wood is scarce,* it constitutes a great deal of ground that might often be cultivated to advantage, and it is not of a lasting quality. Coal is purchased, for several purposes, to every other species of fuel, and besides its domestic application, its superiority for burning lime, that important source of fertility, or calcareous clay, also of much value to the farmer is an object of great moment. The peasant, therefore, who resides in the neighbourhood of coal, more especially if limestone or calcareous substances are at no great distance, gains at his expense, can afford to pay a higher rent, and may derive more profit from the land for cultivation, than if in those respects he were disadvantageously circumstanced.

SECT. VIII. *Extent of Land suitable for a Farm.*

4781 *The extent of ground which a farmer proposes to occupy demands due consideration. If it be beyond his capital to cultivate or improve, he can derive no profit by taking it. On the other hand, a small occupation may not be worthy of his attention.*

4782 *Farms as to size may be divided into three sorts; small farms under 100 acres; moderate-sized farms, from 100 to 200 acres; large farms, from 200 to 1000 acres; and upwards, of land fit for cultivation. The expense of labour is now so great, and the rent of land so high, that the profits of a small farm are not sufficient, with the utmost frugality or even parsimony, to maintain a family with comfort.*

4783 *Moderate-sized farms are well calculated for the dairy system, for the neighbourhood of large towns, and where capital is not abundant. There are few trades in which a small capital can be employed to a greater advantage than in a dairy farm, yet there is no branch of agriculture where such constant and unremitting attention is required. That is not to be expected from hired servants; but it is in the power of the wife and daughters of the farmer to perform, or at any rate to superintend, the whole business, and without their aid it cannot be rendered productive.*

4784 *Moderate-sized farms are general in the neighbourhood of towns. This necessarily results from the high rents paid in such situations, the shortness of the leases usually granted of land near towns; and the necessity the farmer is under of selling, in small quantities, the articles produced on his farm. On this subject it has been remarked, that farmers in the vicinity of large towns resemble retail shopkeepers, whose attention must be directed to small objects, by which a great deal of money is got, the greater part of which would be lost without the most unremitting attention. The farmer at a distance from markets, who cultivates on a great scale, may be compared, on the other hand, to a wholesale trader who, as his profits are less, requires a greater extent of land, for the purpose both of engaging his attention, and of enabling him to support that station of life in which he is placed. There is thus difference also between farmers in the neighbourhood of towns, and those who reside at a distance from them, that the former find it more profitable to sell their produce, even such bulky articles as turnips, potatoes, clover hay, and straw, than to fetch cattle for the butcher, and they are enabled to do so, without injury to their farms as they can procure dung in return.*

4785 *Farms of the largest size differ in respect to the capital required. A mountain breeding farm of 2000 acres will not require more to stock it than an arable farm of 200 acres, and much less expense of labour to carry it on. In all cases the safe side for the farmer to lean to, is to prefer a farm rather under than exceeding his capital, and let him consider well beforehand whether he is going to commence a retail farmer for daily markets, or a manufacturer of produce on a large and ample scale. For the spirit, attention and style of living of the one differs materially from that of the other. — The subject of this section and the two following having been treated in a general way as between landlord and tenant in the preceding chapter will be here only briefly noticed as on the part of the tenant.*

SECT. IX. *Tenures on which Lands are held for Farming.*

4786 *Perpetual tenures, or absolute property in land, can never come into consideration with a farmer looking out for a farm. A proprietor cultivating his own property cannot, in correct language, be said to be a farmer for to constitute the latter an essential requisite is the payment of rent.*

4787 *The leases on which lands are let for farming are for various terms, and with very different covenants. The shortest lease is from year to year, which, unless in the case of grass lands in the highest order, and of the richest quality, or under some other very peculiar circumstances, no prudent man, whose object was to make the most of his skill and capital, would accept of. Even leases for seven or ten years are too short for general purposes: a period of fourteen or fifteen years seems to be the shortest for arable lands, so as to admit of the tenant paying a full rent. But fourteen years, when the lands to be entered on are in bad condition, are too few, and twenty-one years much better for the true interests of both parties. In farming, however, as in every other occupation where there are more skill and capital in want of employment than can find subjects to work on, farms will be taken under circumstances, both in regard to leases and rent, that are highly unfavourable to the farmer, and if they do not end in his ruin will keep him always poor and probably not only pay less interest for his capital than any other way in which he could have employed it, but also infringe on its amount. The rapid depreciation of currency which took place in Britain during the wars against the French deceived many farmers, and fastened them for a time to the gradual rise of markets year after year. However high land might be taken at the commencement of a lease, it was always considered a consolation that it would be a bargain by the time it was half done, and that the farmer's fortune would be made during the last few years of its endurance. When the currency of Britain was permitted to find its level with that of other countries, the delusion ceased, and the majority of farmers were partially or wholly ruined.*

4788 *In regard to the covenants of a lease it is necessary that there should be such in every one as shall protect both landlord and tenant. Certain general covenants in regard to repairs, renewals if necessary, timber, minerals, entry and exit crops, are common to all leases. Regulations as to manure are required where hay and straw and other crops, are sold not to be consumed on the farm. Water meadows, rich old grass lands, copse woods, hay grounds, orchards, &c. require special covenants. Fewest covenants are required for a mountain breeding farm; and in all cases there should be a clause entitling the tenant to an appeal, &c. and a hearing from the landlord, and perhaps a jury of landlords or agents and farmers, against covenants as to cropping, repairs, or renewals, which may from extraordinary circumstances, press particularly heavy on the tenant.*

4789 *The power of a landlord to grant a lease, with liberal conditions, may in some cases be required to be ascertained by the tenant; and in Scotland, where it is illegal to sublet a farm unless a clause to that effect has been inserted in the original lease, a farmer may cease to be the master of his own property unless he has taken care to see this clause inserted. In England, for the most part, subletting a farm is no more prohibited than subletting a dwelling-house or a shop. When the laws of countries shall come to be founded on equity, this will be the case every where. At present they almost every where lean to the side of the powerful party the landlord. In the progress of things it could not be otherwise.*

SECT. X. *Rent.*

4790 *The rent of land, in a general point of view, must always depend on a variety of circumstances: as the wealth of the country, its population; the price of produce; the amount of public and other burdens, the distance from markets; the means of conveyance, the competition among farmers; and other less important considerations: but the rent of any particular farm must be regulated by the nature of the soil; the situation*

of the tenure, and the covenants contained in the lease; the capital to be invested by the farmer in its culture; and the expenses to which he is liable.

6751. The cost of poor land cannot possibly be the same as in the case of fertile lands. The labour of ploughing, harrowing, sowing, &c. when the land is in cultivation, is nearly the same, and yet the produce is greatly inferior, not only in quantity, but in quality. Indeed, where the produce is inconsiderable, or the quality much inferior to the whole, or nearly the whole, may be swallowed up by the expense of labour, and no rent whatever can be afforded, more especially in adverse seasons.

6752. The duration of the tenure must have a considerable effect in fixing the rent. No farmer can afford to pay the same sum for land on a short as if he held it on a long lease. The tenant, also, which serves but a species of rent, must influence the money payment.

6753. Rent must also depend on the capital invested in the cultivation of the farm. Thus, if a farmer can lay out only £1. of capital per acre, he may not be able to afford for it a higher rent than 10s. per acre; if he lays out 7s. he may pay 14s. and with a capital of 10s. per acre, he may be enabled to pay 18s. or 20s. of rent.

6754. The proportion of produce which should be paid as rent, is a question that has long been considered as obscure, uncertain, and very difficult to resolve. Some have supposed that one fifth was a reasonable proportion, while others contend for a fourth, or even a third part of the produce of arable land. But all former calculations on this subject are rendered fallacious by the effects of modern improvements. The rent ought certainly to depend upon the amount of the disposable produce; and that produce in gross is greatly augmented, both by a diminution of the consumption on the farm, effected by improved implements, and a more correct arrangement of labour, and likewise a better cultivation of the land in tillage. Hence, while the price of wheat has greatly advanced during the last twenty years, above the average price of the preceding twenty the rent of land has not only risen, but in a higher proportion. More grain, and that of a better quality has been produced on the same extent of land, and a greater amount of disposable surplus has gone to market. Out of this surplus disposable produce, it is evident that the rent must be paid. But it is difficult to divide its amount between the landlord and tenant, as so much depends upon the seasons, and on the price of the different articles which the farm produces. In bad seasons also, every deficiency of produce, in the acres set apart for supporting human population, must be made up from the disposable surplus: nor is it possible to apply the same rules to all situations, soils, and climates, in all the various districts of an extensive country. It may be proper, however, to give some general idea of the proportion of produce paid as rent in Scotland and in England.

6755. In Scotland, the following table states what is considered to be a fair proportion, where the land is cultivated. One of the most scientific agricultural writers, and, at the same time, one who has had much experience in farming, informs us that "this table is a statement of Sir John Sinclair, who wishes to subject every thing to petty regulation, and that there is no such proportion recognised in Scotland —

Where land produces 100. 10s. per acre per annum, one third, or	Per acre
Where land produces 80. 10s. per acre per annum, one fourth, or	£3 11 0
Where land produces only 60. 10s. per acre per annum, one fifth, or	1 15 0
	0 17 0

6756. As regard to grazing farms, they are let on principles totally different from the arable, namely, according to the quantity of stock they can maintain: and as they are not liable to the same expense of management, both the landlord and the tenant receive larger shares of the produce than in the case of arable farms.

6757. In England, the tenant is allowed, on arable land, what is considered to be one moiety of the surplus, after deducting the expenses of cultivation, the taxes to which he is liable, and every other out-going. His land requires much less of his attention: and for this he only obtains one third of the surplus. But the possessor of grazing depending much on superior judgment in buying and selling stock, as well as skill in preventing or curing liver diseases, the greater is entitled to a share of the surplus, fully equal to that of the landlord. It has been contended, as a general principle, that as each of the extremes of cultivating land, and the value of its produce, are infinitely various, a farmer ought to calculate what profit he can make on his whole farm, without entering into details: it being of little consequence to him whether he pays at the rate of 10s. or 10s. per acre, provided he makes an adequate interest on the capital invested. That is certainly a fair criterion on which a tenant may calculate what he ought to offer; but a landlord, in estimating the rent he ought to insist on, will necessarily take into his consideration the produce that his land is capable of yielding, and what proportion of it, or of its value, at a fair average, he has reason to expect, under all the circumstances of the case.

6758. 7thly. In Scotland there is no tithe. In England, compositions for tithes are computed as six to ten to twenty-two, so is the composition for tithes to the rent: so that land averaging 100. 10s. per acre would, according to Sir John Sinclair's calculation, be charged for

Rent

Composition for tithes

£2 11 7½
19 48
£3 11 0

6759. What the profits are to which a farmer is entitled, is a question much disputed. The proper answer is simply this — The common profits of capital invested in other commercial undertakings. As the subject, however, will be troubling about, let us hear what is said in the Code on this subject. On the one hand it is contended, that the produce of land is of such universal and absolute necessity to the existence of mankind, that it is not reasonable it should yield to him who raises it more than a fair profit. On the other hand it is urged, that a farmer is entitled to be fully recompensed for the application of a considerable capital, exposed to the uncertainty of the seasons, when it is managed with economy and accompanied with industry and skill: and it has also been observed that it is seldom more money is got by farming than on adequate interest for the capital invested. This is owing to competition, the articles produced being in stapleable kinds, who must bring them to market; and necessarily the profit of the farmer being in general of a perishable nature, on the sale of which he depends for the payments he has to make, and the subsistence of his family. To prove how moderate the profits of farming in general are, it appears from the most general accounts, that on arable farms they rarely exceed from ten to fifteen per cent. on the capital invested, which is little enough, considering that few employments are more subject to fluctuations than farming, or require more uniform attention. Some arable farmers, possessors of superior skill and energy, and who have got leave on reasonable terms, may clear from fifteen to twenty per cent. while others, who are deficient in these qualities, or pay too high rents, frequently become in debt. Certain it is, that the great majority of farmers merely contrive to live and bring up their families: adding little or nothing to their capital, but that annual addition which takes place in consequence of the depreciation of the currency.

6760. In grazing farms the case is different; as they are attended with less expense of labour and produce a portion of a more luxuriant description, for which a higher price will be given. Hence, in such farms, fifteen per cent. and upwards is not unusual. Besides, the greater is more of a trader than the more arable farmer: is necessarily buying as well as selling stock: and sometimes makes money by judicious operations, though occasionally, from a sudden fall of stock, his losses are considerable. The greater who usually support stock, and whose labour great expense, is certainly well satisfied to make than common profit for his skill and attention.

4801. *For the mode in which rent should be paid, and the terms of payment, we refer to the succeeding Book.*

# BOOK XI Taxes and other Burdens which affect the Farmer.

4802. *Farmers are subjected to the payment of various taxes besides the rent paid to the landlord; some of them imposed for local purposes, and others for the general expenses of the state. The real amount of such burdens every careful tenant ought accurately to know before he bargains for his lease. They may be classed under the following heads: parochial, national, and miscellaneous.*

4803. *Parochial taxes are for the support of the clergyman, for the maintenance of the poor, and, in Scotland, for providing a parochial schoolmaster. The mode of supporting the clergy in England, by paying them a tenth part of the produce of the land in kind, is highly injurious to agriculture, and a bar to improvement. It is a great bar to improvement, because an improving farmer, one more enlightened or more spirited than his neighbours, would pay more tithes by means of his outlay and his exertions, but it is not certain that he would likewise receive more profit. The produce would be more, but the expense would be greater. Nothing can be more obvious than a law by which, when a person expends a large sum either in reclaiming wastes, or augmenting the fertility of land already cultivated, he should be under the necessity of yielding up one tenth of its produce to a person who has been liable to no share of the expense, who has run none of the risk, and who has sustained none of the labour attending the improvement. A commutation of tithes, therefore, instead of its being a disadvantage, would be one of the greatest benefits that could be conferred on agriculture; and there is not the least difficulty in effecting it, by giving to the tithe-owner either a proportion of the land, or by converting the tithes into a perpetual corn rent. Both these plans have been adopted in a variety of cases, by local acts in England, and they might now be enforced as a general system.*

4804. *An assessment for the maintenance of the poor is another parochial burden which is annually increasing, and which, if not speedily regulated upon proper principles, will inevitably absorb a very large proportion of rent in England. Indeed, there are instances where between the years 1815 and 1823, it has absorbed the whole. This tax is the most dangerous of all for the farmer on account of its fluctuation, and, indeed, it may be said that it never falls, but continually rises. During infancy in sickness, and in old age, assistance may be necessary; but, as Malthus justly observes, the poor-laws hold out support to the vicious and idle, at the expense of the prudent and the industrious. These payments also destroy the spirit of independence, and those ideas of honest pride which stimulate a man to use his utmost exertions in support of himself and his family; and, on its present footing the boon is administered by the parish officers with caution and reluctance, and received by the poor with dissatisfaction and ingratitude.*

4805. *The rates and the poor-rates are charges upon the land, and in fact come from the landlord's pocket rather than from the tenant's; but in their operation are often oppressive to the tenant, by raising in the course of the lease much higher than they were at the commencement, and as a farmer's rent is always considered by the overseer to be his income, he is charged on that; while the tradesman who realises three times the amount, is only charged to the poor on the amount of rent of his house.*

4806. *In Scotland, the poor are in general maintained by voluntary contributions; but when these are not found to be sufficient, the proprietors of the parish with the clergyman and vestry or kirk-session, are directed to make a list of the indigent persons in the parish, and then to impose an assessment for their relief, one half to be paid by the proprietors, and the other half by the tenantry.*

4807. *The national burdens in general, as the duties on houses and windows, and other assessed taxes, or assessments for the support of militia-men's wives and families, for the conveyance of vagrants, or the prosecution of felons, fall so heavily upon the farmer than upon other classes of the community.*

4808. *There are several gentlemanly burdens affecting the farmer as estate assessments for bridges, which are of much public utility that moderate rates for their maintenance, properly applied, cannot be objected to; statute labour on the highways; constable dues which are seldom of much moment; charges of the churchwardens, including the repairs of the church; and in some populous parishes, there is sometimes a burial-ground tax. All these are paid by the occupiers. In some places, also, there is a sewer tax, chargeable on the landlords, where it is not otherwise settled by express contract.*

4809. *The assessments to which farmers in England are subjected, from various uncertain burdens, operate as a premium to Scottish agriculture. It is ingeniously and justly remarked, that physical circumstances are much more favourable to agriculture in England than in her sister country; but these advantages are counteracted by the accumulation of moral evils, which might be removed if the legislature were to bestow on matters connected with the internal improvement of the country, and the means for promoting it, a portion of that attention which it so frequently gives to the amelioration or improvement of our social possessions. It ought to have been the business of the late Board of Agriculture to endeavour to prevail on the legislature to relieve agriculture from its moral and political evils; but, instead of this, they set about procuring and distributing statistical and professional information, comparatively of very inferior utility, and after receiving from government nearly 50,000*l.* for any thing we know more, left agriculture where they found it. Even in the particular line which the Board adopted, Marshall was a much more effectual instrument of agricultural improvement.*

## BOOK XII Other Particulars requiring a Farmer's Attention, with a View to the Renting of Land.

4810. *A variety of miscellaneous particulars require consideration before a prudent farmer will finally resolve to undertake the cultivation of a farm; as, the nature of the property on which the farm is situated; in particular, whether the estate is entailed, and to what extent the possessor of the estate is authorised to grant a lease; the character of the landlord, and, in case of his decease, that of his family, and of those whom they are likely to consult; the real condition of the farm in regard to the enclosures, drainage, buildings, &c. the crops it has usually produced, and the manner in which it has been managed for some years preceding; the general state of the district, in regard to the price of labour and the expense of living; the character of its inhabitants, in particular of the neighbouring farmers and labourers, and whether they are likely to promote or to discourage a spirit of improvement; the probability of subletting to advantage in case of not liking the situation, of finding a better bargain, or of death. The chances of settling one's family; or of marrying daughters, or of sons making good marriages. The social state of the farmers, or those that would be considered one's neighbours; the number and*

time of clergy, and lawyers; the game, and the chances of disputes concerning it; the morals of the serving class; schools, places of worship, &c. It is evident, that in hardly any one instance are all the circumstances above enumerated to be favourably combined. But the active and intelligent farmer will not be discouraged by the obstacles he may have to surmount; but will strenuously endeavour, by exertion, industry, and perseverance, to overcome the difficulties he must unavoidably encounter. These are vague generalities, and may be thought too commonplace for a work of this description; but the young farmer on the look-out for a farm may not be the worse for having his memory refreshed by them.

## CHAP. II.

*Considerations respecting Himself, which a Farmer ought to keep in view in selecting and hiring a Farm.*

4811 *Whoever intends to embrace farming as a profession, will be less likely to meet with disappointment, if he previously examines a little into his own disposition and talents and weighs his expectations against ordinary results. Nor is it less essential that he should estimate justly the extent to which his capital may be adequate, and keep regular accounts.*

### SECT. I. Personal Character and Expectations of a professional Farmer.

4812 *Every one who proposes to farm with success, Professor Thier observes, ought to unite energy and activity, to reflection, to experience, and to all necessary knowledge. It is true, he says, farming has long been considered as an occupation fit for a young man incapable for any other, and such have sometimes succeeded; but this has always been chiefly owing to a fortunate concurrence of circumstances, which it is not now very easy to meet with.*

4813 *The professor of agriculture consists of an infinite number of particular operations, each of which appears easy in itself, but is often for that very reason the more difficult to execute to the precise extent required. One operation so often interferes with another. To regulate them according to the given time and strength, and in such a way that none is neglected, or causes the neglect of others, requires at once a great deal of attention and activity without intermission of promptitude without precipitation of general views, and yet with an extreme attention to details.*

4814 *To consider and conduct no business is so much exposed as farming; and therefore, to enjoy an ordinary degree of happiness, Professor Thier considers it essential that the farmer possess a certain tranquillity of mind. This, he says, may either be the result of a naturally phlegmatic habit of body or of elevated views in religion or philosophy. These will enable him to bear with every misfortune arising from adverse seasons, or the death of live stock; and only permit him to regret accidents which result from his own neglect.*

4815 *The expectations of profit and happiness which a young farmer has formed ought to be well weighed against the profits and happiness of farmers in general. However superior a farmer may consider his own talents and abilities, he may rest assured there are a number as skilful and ardent as himself and just as likely to realise extraordinary advantages. Let none therefore engage in farming, thinking to make more money than other farmers similarly circumstanced with himself. If from a happy concurrence of circumstances he is more than usually successful, so much the better; and let him consider it as yearly coming to good fortune as well as good farming; but never let him set out on the supposition of gaining extraordinary advantages with only ordinary means.*

4816 *The profits of farming are much exaggerated by people in general; but it may be asserted as an unquestionable fact, that no capital affords less profit than that employed in farming, except that sunk in landed property. This is the natural result both of the universality of the business and of its nature. Farming is every where practised, and every one thinks he may easily become a farmer; hence high rents, which necessarily lessen the profits on capital. From the nature of farming, the capital employed is returned seldom. A tradesman may lay out and return his capital several times a year; but a farmer can never, generally speaking, grow more than one crop per annum. Suppose he succeeds in raising the best possible crops in his given circumstances, still his profits have an absolute limit. For if an ordinary crop be an five, and the best that can be grown be as seven, all that the most fortunate concurrence of circumstances will give is not great, and is easily foreseen. It is hardly possible for a farmer, paying the market price for his land, to make much more than a living for himself and family. Those few who have exceeded this, will be found to have had leases at low rents; indulgent landlords; to have profited by accidental rises in the market, or depreciation of currency; or to have become dealers in corn and cattle, and mostly indeed to have realised any thing considerable by more good culture of a farm at the market price. Very different is the case of a tradesman, who, with the properties which we have mentioned as requisite for a good farmer seldom fails of realising an independency.*

4817 *Many persons, charmed with a city life, or tired of their profession, fancy they will find profit and happiness by retiring to the country and commencing farming. Independently of the pecuniary losses attending such a change, none is more certain of being attended with disappointment to the generosity of men. The society required, and the privations that must be endured, are too painful to be submitted to; whilst the self-sufficiency of a farmer's life to one accustomed to the bustle of cities, is often intolerable to such as do not find resources in their friends, their own minds, or as Professor Thier observes, in the study of nature.*

4818 *The most likely persons to engage in farming with success are the sons of farmers, or such others as have been regularly brought up to the practice of every part of agriculture. They must also have an inclination for the profession, as well as a competent understanding of its theory or principles. Books are to be found every where, from which the science of the art is to be obtained; and there are numerous farmers in the improved districts who take apprentices as pupils.*

4819 *In The History of Scotland, the case is mentioned of Walker, of Mallowden, an excellent*

farmer of Roxburghshire, renting about 3000 acres of arable land, and distinguished for his skill in agriculture, who takes young men under him as apprentices, and these, instead of receiving wages, have annually paid him ten pounds each. Some of them remain with him two years, but the greater number only one. They eat in his kitchen, where they have always plenty of plain wholesome food. He takes none who are above living in that way, or who will not put their hands to every thing going forward on the farm. He has sometimes been offered ten times the above sum, to take in young gentlemen to eat and associate with his own family but that he has uniformly declined. These young men have an opportunity of attending to every operation of husbandry as practised on Walker's farm; and are taught to hold the plough, to sow to build stacks, &c.

#### SECT. II. Capital required by the Farmer

4820 *The importance of capital in every branch of industry is universally acknowledged, and in none is it more requisite than in farming. When there is any deficiency in that important particular, the farmer cannot derive an adequate profit from his exertions, as he would necessarily be frequently obliged to dispose of his crops for less than their value, to procure ready money, and it would restrain him from making advantageous purchases, when even the most favourable opportunities occurred. An industrious, frugal, and intelligent farmer, who is punctual in his payments, and hence in good credit, will strive with many difficulties, and get on with less money than a man of a different character. But if he has not sufficient live stock to work his lands in the best manner, as well as to raise a sufficient quantity of manure nor money to purchase the articles required for the farm he must, under ordinary circumstances, live in a state of penury and hard labour and the first unfavourable season, or other incidental misfortune, will probably sink him under the weight of his accumulated burdens. Farmers are too generally disposed to engage in larger farms than they have capital to stock and cultivate. This is a great error, for it makes many a person poor upon a large farm, who might live in comfort and acquire property upon one of less extent. No tenant can be secure without a surplus at command, not only for defraying the common expenses of labour but those which may happen from any unexpected circumstance. When a farmer farms within his capital, he is enabled to embrace every favourable opportunity of buying when prices are low, and of selling when they are high.*

4821 *The amount of capital required must depend upon a variety of circumstances as whether it is necessary for the farmer to expend any sum in the erection or in the repair of his farm house and offices what sum an in-coming tenant has to pay to his predecessor for the straw of the crop, the dung left upon the farm, and other articles of similar nature the condition of the farm at the commencement of the lease, and whether any sums must be laid out in drainage, enclosure, irrigation, levelling ridges, &c. whether it is necessary to purchase lime, or other extraneous manures, and to what extent on the period of entry, and the time at which the rent becomes payable, as this is sometimes exacted before there is any return from the lands, out of the actual produce of which it ought to be paid and, lastly, on its being a grazing or an arable farm, or a mixture of both.*

4822 *In pasture districts, the common mode of estimating the amount of capital necessary is according to the amount of the rent and it is calculated that, in ordinary pastures, every farmer ought to have at his command from three to five times the rent he has agreed to pay. But in the more fertile grazing districts carrying stock worth from 30*l*. to 30*l*. and even upwards, per acre (as is the case in many parts of England) five rents are evidently insufficient. When prices are high, ten rents will frequently be required by those who breed superior stock, and enter with spirit into that new field of speculation and enterprise.*

4823 *The capital required by an arable farmer varies, according to circumstances, from 5*l*. to 10*l*. or even 15*l*. per acre. An ignorant, timid, and penurious farmer lays out the least sum he can possibly contrive, and consequently he obtains the smallest produce or profit from his farm. The profit, however will always increase, when accompanied by spirit and industry in proportion to the capital employed, if judiciously expended. At the same time, attention and economy cannot be dispensed with. It is ill-judged to purchase a horse at forty guineas, if one worth thirty can execute the labour of the farm or to lay out sums unnecessarily upon expensive harness, loaded with useless ornaments. Prudent farmers also, who have not a large capital at command, when they commence business, often purchase some horses still fit for labour though past their prime, and some breeding mares, or colts, and in five or six years, they are fully supplied with good stock, and can sometimes sell their old horses without much loss. In every case, such shifts must be resorted to, where there is any deficiency of capital.*

4824 *A mixture of arable and grass farming is, on the whole, the most profitable method of farming. Independently of the advantages to be derived from the alternate husbandry (which are always considered) the chances of profit are much more numerous from a varied system than where one object is exclusively followed. Where this mixed mode of farming is practised, the farmer will frequently rely on the increase of lean stock, instead of breeding his own, and derives great advantage from the quickness with which capital thus employed is returned. But, in that case, much must depend upon judicious selection. In general it may be said, that to stock a turnip-land arable farm, will require, at this time (1830), 3*l*. or 4*l*. and a clay land farm from 7*l*. or 8*l*. per acre, according to circumstances.*

4825 *The capital is necessarily divided into two parts. The one is partly expended on implements, or stock of a more or less perishable nature, and partly vested in the soil for this the farmer is entitled to a certain annual gain, adequate to replace, within a given number of years, the sum thus laid out. The other is an expense in defraying the charges of labour &c. as they occur throughout the year; the whole of which with the interest, should be replaced by the yearly produce. These two branches of expense on a farm are the first to be attended to, both in order of time, and in magnitude of amount.*

## CHAP. III.

## Choice of Stock for a Farm.

4826. The stocking of a farm may be considered as including live stock, implements, servants, and seed. A considerable portion of a farmer's capital is employed in manures, tillage, labour, &c., but a farm being once engaged, the above are the only descriptions of stock which admit of a choice.

## SECT. I. Choice of Live Stock.

4827. The animals required by a farmer are of two kinds, such as are employed to assist in labour and such as are used to convert the produce of the farm into food, or other disposable commodities.

## SECT. I. Live Stock for the Purposes of Labour.

4828. The animals of labour used in British farming are exclusively the horse and the ox. Much difference of opinion formerly prevailed, as to which of these two animals should be preferred and the preference has generally been given by speculative writers to the ox, and by practical farmers to the horse. Lord Kaimes in the last century, and Lord Somerville in the present, may be considered the principal advocates for the ox. To their arguments, and to all others, the following objections have been stated by the able author of the supplement to the 6th edition of *The Gentleman Farmer*; and they may be considered as conveying the sentiments, and according with the practice, of all the best informed and most extensive British farmers.

4829. The first objection to oxen is, that they are unfit for the various labours of modern husbandry, — for travelling on hard roads in particular — for all distant carriages, — and generally for every kind of work which requires despatch. And what sort of work often does not in this variable climate? A great part of a farmer's work is indeed carried on at home, and it may still be thought that this may be done by oxen, while one or more horse teams are employed in carrying the produce to market, and bringing home manure and fuel. But it is unnecessary to appeal to the author of *The Wealth of Nations*, to prove the impracticability of this division of labour, unless upon very large farms and even on these the advantages of such an arrangement are at best extremely problematical. The different kinds of farm-work do not proceed at the same time; but every season, and even every change of weather, demands the farmer's attention to some particular employment, rather than to others. When his teams are capable of performing every sort of work, he brings them all to bear for a time upon the most important labours of every season; and when that is despatched, or interrupted by unfavourable weather the less urgent branches are speedily executed by the same means. This is one cause, more important perhaps than any other, why oxen have ceased to be employed for even ploughing, which they can perform better than any other kind of work, or sowing ever going forward all the year and for some months in winter the weather often prevents it altogether.

4830. Another objection is, that an ox team, capable of performing the work of two horses, even such kind of work as they can perform, consumes the produce of considerably more land than the horses. If this be the case, it is of no great importance, either to the farmer or the community, whether the land be under oats, or under husbandry and roots. The only circumstance to be attended to here is, the quantity of the ox: the value of that, in stating the consumption of produce, must be added to the value of his labour. He sometimes, from his birth till he goes to the shambles, the produce of a certain number of acres of land: the return he makes for this is so much beef and so many years' labour. The consumption of produce must therefore be divided between these two articles. To find the share that should be allotted to each, the first thing is to ascertain how many acres of grass and roots would produce the same weight of beef from an ox, bred and reared for beef alone, and slaughtered at three or four years old. What quantity has been consumed in producing labour. The next thing is to compare the consumption with that of the horse, which produces nothing but labour. By this simple test, the question, viewing it upon a broad national ground, must evidently be determined. Every one may easily make such a calculation suited to the circumstances of his farm; none that could be offered would apply to every situation. But it will be found, that if even three oxen were able to do the work of two horses, the advantages in this point of view would still be on the side of the horse; and the first objection applies with undiminished force thenceforward.

4831. The money-price of the horse and ox, it is evident, is merely a temporary and incidental circumstance, which depends upon the demand. A work ox may be got for less than half the price of a horse, because there is little or no demand for working oxen while the demand for horses by manufacturers, sumptuous, pleasure, and war increases the price of farm-horses, as well as of the food they consume. Those who wish to see horses bred from all sorts of agricultural labour would do well to consider when they see to be reared for the numerous wants of the other classes of society. Besides, if two oxen must be kept for doing the work of one horse, it ought to be foreseen, that though beef may be more abundant than at present, there will be a corresponding deficiency in the production of mutton and wool. A greater portion of the arable land of the country must be withdrawn from yielding the food of man directly and kept under cattle crops, which, however necessary to a certain extent for preserving the fertility of the soil, do not return highest food, on a comparison with green crops, in so great a proportion as that of one to six from any given extent of land of the same quality.

4832. The demand for oxen is confined almost every where to the shambles; and by the improvements of modern husbandry, they are brought to a state of profitable maturity at an early age. No difference in price at setting to work, — no increase of weight while working, — no saving on the value of the food consumed, can ever make it the interest of tillage farmers generally to keep oxen as formerly, till they are eight or ten years old. They judiciously obtain the two products from different kinds of animals, each of them from the kind which is best fitted by nature to afford it, — the labour from the horse and the beef alone from the ox. And though the price of the horse is almost wholly sunk at last, during the period of his labour he has been paying a part of it every year to a fund, which, before his usual term expires, becomes sufficiently large to indemnify his owner. The ox, on the other hand, is changed three or four times during the same

period; and each of them gives nearly as large a carcass for the food of man as if his days had been unprofitably prolonged in execrating labour, from which he has been gradually exempted in Britain, in France, and in other countries, very nearly in proportion to the progress of correct systems of husbandry.

4853. *The description of horse which a farmer ought to choose will depend chiefly on the soil of the farm, and partly also on the quantity of road-work.* Stiff lands require obviously a heavier and more powerful breed than such as are light and hilly. In the latter case, two of the best breeds are the Cleverlands and Clydesdals, or some local cross with these breeds. In general, it is not advisable to procure horses from a climate materially different from that where they are to remain, and therefore, for various reasons, a prudent farmer will look out for the best in his neighbourhood. Often, however, he is obliged to take the stock of his predecessor and this he can only get rid of or improve to his mind by degrees. The farm-horses in most parts of England are much too cumbersome and heavy, and are more fitted for drawing heavy drays or waggons in towns than for the quick step required in the operations of agriculture.

4854. *The objections of Davis of Longport to the using of large heavy-bodied horses, in preference to the smart, the active, and the really useful breeds, merit particular attention.* In some situations, the steepness of the hills and the heaviness of the soil require more than ordinary strength; but, in such cases, he maintains that it would be better to add to the number of horses than to increase their size. Great horses not only cost proportionably more at first than small ones, but require much more food, and of a better quality, to keep up their flesh. The Wiltshire owner also takes a pride in keeping them as fat as possible and thereby food (which is generally barley) is given without stint. In many instances, indeed, the expense of keeping a fine team of horses amounts nearly to the rent of the farm on which they are worked. They are purchased young when two years' old colts, and sold at five or six years of age for the London drays and waggons. The expense of their maintenance is very seldom counterbalanced by the difference of price, more especially as such horses are gently worked when young that they may attain their full size and beauty. In weighing light soils, the strength of a dray-horse is not wanted; and in heavy soils, the weight of the animal does injury to the land.

#### SUMMARY 2. Choice of Live Stock for the Purpose of breeding or feeding

4855. *The most desirable properties of live stock destined for food are considered in The Code of Agriculture, in respect to size, form, a tendency to grow, early maturity, hardness of constitution, prolific properties, quality of flesh, a disposition to fatten, and lightness of offal.*

4856. *The bulk of an animal was the sole criterion of its value before the improvements introduced by Bakewell; and if a great size could be obtained, more regard was paid to the price the animal ultimately fetched than to the cost of its food.* Of late, since breeders began to calculate with more precision, small or moderate-sized animals have been generally preferred, for the following reasons:—

4857. *Small-sized animals are more easily kept, they thrive on shorter herbage, they collect food where a large animal could hardly exist, and thence are more profitable.* Their meat is finer grained, produces richer gravy, has often a superior flavour, and is commonly more nicely marbled, or veined with fat, especially when they have been fed for two years. Large animals are not so well calculated for general consumption as the moderate-sized, particularly in hot weather. Large animals pouch pasture more than small ones: they are not so active, require more rest, collect their food with more labour, and will only consume the milder and more delicate sorts of plants. Small cows of the true dairy breeds give proportionably more milk than large ones. Small cattle may be fattened solely on grass of even moderate quality; whereas the large require the richest pasture, or to be stall-fed, the expense of which exhausts the profit of the farmer. It is much easier to procure well-shaped and kindly-behaving stock of a small size than of a large one. Small-sized cattle may be kept by many persons who cannot afford either to purchase or to maintain large ones, and their loss, if any accident should happen to them, can be more easily borne. The small-sized sell better; for a butcher from a conviction that, in proportion to their respective dimensions, there is a greater superficies of valuable parts in a small than a large animal will give more money for two oxen of twelve stone each per quarter than for one of twenty-four stone.

4858. *In favour of the large-sized it is, on the other hand, contended, that without deciding whether from their birth till they are slaughtered the large or the small one eats most for its size, yet on the whole the large one will pay the grazer or the farmer who fattens him as well for his food; that though some large oxen are coarse-grained, yet where attention is paid to the breed (as in the case with the Herefordshire) the large ox is as delicate food as the small one; that if the small-sized are better calculated for the consumption of private families, of villages, or of small towns, yet that large oxen are fatter for the markets of great towns, and in particular of the metropolis; that were the flesh of the small-sized ox better when fresh, yet the meat of the large-sized is unquestionably more calculated for salting, a most essential object in a maritime and commercial country—for the thicker the beef, the better it will retain its juices when salted, and the fatter it is for long voyages; that the hide of the large ox is of very great consequence in various manufactures; that large stock are in general distinguished by a greater quickness of disposition; that where the pastures are poor, cattle and sheep will increase in size, without any particular attention on the part of the breeder; large animals are therefore naturally the proper stock for such pastures; that the art of fattening cattle, and even sheep, with oil-cakes, being much improved and extended, the advantages of that practice would be of less consequence, unless large oxen were bred, as small ones can be fattened with grass and turnips as well as oil-cakes; and, lastly that large oxen are better calculated for working than small ones, two large oxen being equal to four small ones in the plough or the cart.*

4859. *Such are the arguments generally made on both sides of the question.* From which it appears that much must depend upon pastures, time, mode of consumption, markets, &c. and that both sides have their advantages. The intelligent breeder, however, (unless his pastures are of a nature peculiarly forcing,) will naturally prefer a moderate size in the stock he rears. Davis of Longport, one of the ablest agriculturists England has produced, has given some useful observations on the subject of size. He maintains that the attempts which have been made to improve the breeds of cows, horses, and sheep, have proceeded too much upon the principle of enlarging the size of the animal; whereas, in general, the only real improvement has been made in the pig, and that was by reducing its size and introducing a kind that will live harder, and come to greater perfection at an earlier age.

4860. *Though it is extremely desirable to bring the shape of cattle to as much perfection as possible, yet profit and utility ought not to be sacrificed for mere beauty which may please the eye, but will not fill the pocket; and which, depending much upon caprice, must be often changing.* In regard to form, the most experienced breeders seem to concur in the following particulars:—That the form or shape should be compact, so that no part of the animal should be disproportioned to the other parts, and the whole should

be distinguished by a general shape and symmetry of shape; that the chest should be broad, for as chest there chest is heavier can easily be made fat; that the curves should be deep and straight; that the belly should be of a moderate size; for when it is more capacious than common in young animals, it shows a flaccid state, and in other cases it is considered a proof that the animal will not return in flesh, in milk, or in labour, the value of the entire quantity of food which it consumes; that the legs should be short, for the long-limbed individuals of the same family or race are found to be the least hardy and the most difficult to rear or to fatten; and that the head, the bones, and other parts of the skeleton, should be so small as to be consistent with strength, and with the other properties which the animal ought to possess in animals bred for the slaughter, the form must likewise be such as to contain the greatest possible proportion of the flesh, compared with the coarser and less valuable parts of the animal. This, by selection, may be attained, and thus the wishes of the consumer may be gratified. As to the broad loins, and full hips, which are considered as a point of excellence in particular breeds, it is evident that the old sows and thin males required improvement, but the attention is now carried to a fleshy snout, and often corners great difficulty and danger in salting.

6941. The form of animals has fortunately attracted the attention of an eminent surgeon, Henry Clive, Esq. of London, whose doctrines we have already laid down at length, and the substance of which is — That the external form is only an indication of the internal structure; that the lungs of an animal form the first object to be attended to, for on their size and condition the health and strength of an animal principally depend; that the external indications of the size of the lungs are the form and size of the chest, and its breadth is particular that the head should be small, so by thus the birth is facilitated; so it affords other advantages in feeding, &c., and as it generally indicates that the animal is of a good breed, that the length of the back should be in proportion to the size of the animal, that it may collect its food with ease; and that the muscles and tendons should be large, by which an animal is enabled to travel with greater facility. It was formerly the practice to estimate the value of animals by the size of their bones. A large bone was considered to be a great merit; and a fine-boned animal always implied great size. It is now known that this doctrine was carried too far. The strength of the animal does not depend upon the bones, but on the muscles and when the bones are disproportionately large, it indicates, in Clive's opinion, an imperfection in the organs of nutrition. Bakewell strongly insisted on the advantage of small bones, and the celebrated John Russell declared, that small bones were generally attended with competence in all the subjects he had an opportunity of examining. A small bone, however, being heavier and more substantial, requires as much nourishment as a hollow one with a larger circumference.

6942. Among the qualities for which thorough-bred cattle and sheep are distinguished, that of being good growers, and having a good length of frame, is not the least essential. The meaning of which is, that the animal should not only be of a strong and healthy constitution, but especially should grow to a proper size. An instance of rapid growth, a year of three years old, will weigh from 80 to 100 or 120 stone, 14lb. to the stone, and a two-year old Leicester wether from 25 to 35lb. per quarter immediately after his second fleece is taken from him. Animals having the property of growing, are usually straight in their back and belly; their shoulders well thrown back, and their belly rather light than otherwise. At the same time, a gauneness and poverty of intestines should be guarded against, as a most material defect, indicating a very unthriving animal. Being too light of bone, as it is termed, is also a great fault. A good grower, or heavy animal, has always a middle-sized bone. A bull distinguished for getting good growers is inestimable; but one whose property takes an unnatural or gigantic size ought to be avoided.

6943. Arriving soon at perfection, not only in point of growth or size, but in respect of fitness, is a material object for the farmer as his profit must in a great measure depend upon it. Where animals, bred for the carcass merely become fat at an early age, they not only return sooner the price of their food, with profit to the feeder, but in general, also, a greater value for their consumption than slow feeding animals. This desirable property greatly depends on a mild and docile disposition, and as this docility of temper is much owing to the manner in which the animal is brought up, attention to insure them early to be familiar cannot be too much recommended. A blood-bred also has other advantages. It is not so apt to injure fences, or to break into adjacent fields; consequently it is less liable to accidents, and can be reared, improved, and fattened at less expense. The property of early maturity, in a populous country where the consumption of meat is great, is extremely beneficial to the public, as it evidently tends to furnish greater supplies to the market; and this property to attain at an early age is a sure proof that an animal will attain speedily at a later period of his life.

6944. The preservation of a hardy and healthy constitution, is, in the winter and bleaker parts of a country, a most valuable property in stock. Where the surface is barren, and the climate rigorous, it is essential that the stock bred and maintained there should be able to endure the severities and vicissitudes of the weather as well as scarcity of food, hard frosts, or any other circumstance in its treatment that might subject a more delicate breed to injury. In this respect, different kinds of stock greatly vary; and it is a matter of much consequence to select, for different situations, cattle with constitutions suitable to the place where they are to be kept. It is a popular belief, that dark colours are indications of hardiness. In mountain breeds of cattle, a rough pile is reckoned a desirable property more especially when they are to be kept out all winter. It enables them to face the storm, instead of shivering from it. Hardy breeds are exempted from various diseases, such as having yellow fat, and being black-headed, defects so injurious to stock.

6945. The prolific quality of a breed is a matter deserving attention. The females of some breeds both bear more frequently than usual, and also have frequently more than one at a birth. This property runs more strikingly in sub-varieties, or individual families; and though partly owing to something in the habits of animals, and partly to their previous good or bad treatment, yet in some degree seems to depend upon the season, some years being more distinguished for twins than others. In breeding, not only the number, but the sex of the offspring, in some cases, seems to depend upon the female parent. Two cows produced fourteen females each in thirteen years, though the bull was changed every year. It is singular, that when they produced a bull calf, it was in the same year. Under similar circumstances, a great number of males have been produced by the same sows in succession, but not to the same extent.

6946. By the quality of their flesh, breeds are likewise distinguished. In some kinds it is coarse, hard, and stringy; in others of a finer grain or texture. In some breeds, also, the flavour of the meat is superior; the gravy they produce, instead of being white and insipid, is high coloured, well flavoured, and rich; and the fat is intermixed among the fibres of the muscles, giving the meat a streaked, or marbled appearance. Breeds whose flesh have these properties are peculiarly valuable. Hence two animals of nearly the same degree of fatness and weight, and who could be fed at nearly the same expense to the butcher, will sell at very different prices, merely from the known character of their meat.

6947. A disposition to fatten is a great object in animals destined for the slaughter. Some animals possess this property during the whole progress of their lives, while in others it only takes place at a more advanced period, when they have attained their full growth, and are furnished at the same time with a suitable supply of food. There are in this respect other distinctions — most sorts of cattle and sheep, which have been bred in fertile countries, will become fat on a moderate pasture, on which the more refined breeds would hardly live; some animals take on fat very quickly, when the proper food has been supplied, and some individuals have been found, even in the same breed, which have, in a given time, consumed the same individual weight of the same kind of food, yet have become fat at the quickest rate. Even in the human race, with little food, some will grow immediately corpulent. It is possibly from internal combination that this property of quickly becoming fat is derived.

6948. The advantages and disadvantages of fattening cattle and sheep, at least to the extent frequently practised at present, are points that have of late attracted much public attention. But any controversy

on that subject can only arise from want of proper discrimination. Fat meat is unquestionably more nourishing than lean, though to digest this oily matter there are required, on account of its difficult solubility a good bile, much saliva, and a strong stomach, consequently none, except those who are in the most vigorous state of health, or who are employed in hard labour can properly digest it. Though fat meat, however is useful for general consumption, yet experiments in the art of fattening animals are likely to promote useful discoveries; and though, in the course of trying a number of experiments, errors and excesses may be committed, yet on the whole advantage may be derived from the knowledge thus to be obtained. As the bone also gains but little in the fattening animal, and the other offal becomes proper for use, as the animal becomes more fat, the public has not sustained much loss by over-fattening animals. To kill even hogs till they are thoroughly fat, is exceeding bad economy. An ox or sow though the little flesh it has may be of good quality yet presents, when lean, little but skin and bone and if slaughtered in that state, would neither indemnify the owner for the expense of breeding and maintaining it, nor benefit the public. A coarse and heavy-fleshed ox which would require a very long time and much good food to fatten, may be slaughtered with most advantage while rather lean. It is not, however so much the extent of fat, as the want of a sufficient quantity of lean flesh of which the consumer complains for it cannot be doubted, that the lean flesh of a fat animal is better in quality and contains more nourishment, than the flesh of a lean animal.

4490. *Handling wool.* The graziers and butchers in various parts of the kingdom have recourse to feeling the skin, or cellular membrane, for ascertaining a disposition to fatten and since Bakewell directed the public attention so much to breeding, that practice has become more generally known. Handling cannot easily be defined and can only be learned by experience. The skin and flesh of cattle when handled, should feel soft to the touch, somewhat resembling that of a mole but with a little more resistance to the finger. A soft and mellow skin must be more pliable, and more easily stretched out, to receive any extraordinary quantity of fat and muscle, than a thick or tough one. The rigid skinned animal must, therefore, always be the most difficult to fatten. In a good sheep, the skin is not only soft and mellow, but in some degree elastic. Neither cattle nor sheep can be reckoned good, whatever their shapes may be, unless they are first-rate basallers. The improved short-horned breed, besides their mellowness of skin are likewise distinguished by softness and silkiness of hair.

4490. *Lightness of offal.* An animal solely bred for the shambles should have as little offal or parts of inferior value, as possible (consistently with the health of the animal), and consequently a greater proportion of meat applicable as food for man. This, therefore, the skilful farmer will also keep in view in selecting his species of stock. (*Code &c*)

4491. *The Rev. Henry Berry* who has paid much attention to the subject of breeding and feeding cattle, and written several valuable papers on the subject in the *British Farmer's Magazine*, seems to prefer for general purposes the improved short-horns. "These cattle," he says, at three years old, are equal to Hereford cattle at four years old and they are bred from cows which prove much more profitable for the dairy than the Herefords. At the same time, he admits that the Hereford cattle are excellent to purchase with a view to fattening because in a lean state at four years old they will of course not bear an increased price in proportion to the increased time required to render one of them equal to a short-horn of three years. For breeders, therefore, he decidedly recommends the short-horns and he has given an interesting history of this breed of cattle for the last eighty years, the period which has elapsed since it attracted attention. It was imported from Holland to the banks of the Tees or at least, it is the result of a cross between the breed so imported and the native breed of that district. (*Improved Short-Horns, &c.* By the Rev. Henry Berry 2d edit. 1830)

## SECT. II Choice of Agricultural Implements, Seeds, and Plants.

4492. *The variety and excellence of agricultural implements* is so great, that the prudent farmer in regard to these, as well as in every other branch of his art, must study economy. He should not incur an unnecessary expense in buying them, or in purchasing more than are essentially requisite, and can be profitably used. This maxim ought to be more especially attended to by young improvers, who are often tempted, under the specious idea of diminishing labour and saving expense, to buy a superfluous quantity of implements, which they afterwards find are of little use. (*Coventry's Disc. p 47*) It is remarked by an intelligent author on matters of husbandry, that a great diversity of implements, as they are more rarely used, prove in general a source of vexation and disappointment, rather than of satisfaction, to the farmer.

4493. *The different implements required by the farmer* are those of tillage, for drilling or sowing corn for reaping corn for harvesting corn for threshing and cleaning corn for mowing and harrowing hay of conveyance for drawing for harnessing stock for rolling land for the dairy and for miscellaneous purposes.

4494. *In purchasing implements* the following rules are to be observed they should be simple in their construction both that their uses may be more easily understood, and that any common workman may be able to repair them when they get out of order, the materials should be of a durable nature, that the labour may be less liable to interruption from their accidental failure, their form should be firm and compact, that they may not be injured by jolts and shaking and that they may be more safely worked by country labourers, who are but little accustomed to the use of delicate tools. In the larger machines, symmetry and lightness of shape ought to be particularly attended to for a heavy carriage, like a grass mow, is worn out by its own weight nearly as much as by what he carries. The wood should be cut up and placed in a position the best calculated to resist pressure and moisture, so likely to weaken the wood, should, as much as possible be avoided at the same time, implements should be made as light as is consistent with the strength that is necessary. Their price should be such, that farmers in moderate circumstances can afford to buy them yet for the sake of a low price, the judicious farmer will not purchase articles either of a shabby fabric or a faulty form and implements ought to be suited to the nature of the country, whether hilly or level, and more especially to the quality of the soil for these which are calculated for light land will not answer equally well in soils that are heavy and adhesive. (*Code,*)

4495. *In the choice of seed corn,* regard must be had to procure it from a suitable soil and climate, and of a suitable variety. A change from one soil to another of a different

quality, is generally found advantageous but this is not always the case as to climate. Thus, some of the varieties of oats, as the Angus oat, which answers well in most parts of Scotland, is found not to fill in the ear, but to shrivel up after blossoming, in the south of England. In like manner, the woolly-chaffed white wheats of Essex and Kent rot in the ear when grown in the moist climate of Lancashire. In settling on a farm in a country with which the farmer is little acquainted, he will often find it advisable to select the best seed he can find in the neighbourhood, and probably to re-sift it and free it from the seeds of weeds and imperfect grains. Particular care is requisite in selecting the seed of the bean and pea, as so crop depends more on the variety being suited to the soil and climate. Thus, on hot gravelly soils in the south, the late grey pea would produce little haulm and no pulse but the early varieties, or the pearl pea, will produce a fair proportion of both.

4556. *The only small seeds* the farmer has to sow on a large scale, are the clovers, grasses, the different varieties of turnip, and probably the mangold wurtzel and carrot. No expense or trouble should be spared to procure the best turnip seed as if that is either mixed by impregnation with other varieties of the *Brassica* tribe, or has been raised from a degenerate small-rooted parentage, the progeny will never come to any size. The same may be said of carrot or mangold seed, raised from small misshapen roots. Even rape seed should be raised from the strongest and largest rooted plants as these always produce a stronger progeny.

4557. *The selection and propagation of improved agricultural seeds* has till lately been very little attended to. But the subject has been taken up by Mr Sinclair of New Cross, Mr Shurreff of Mungos Wells, Mr Gornie of Hale, and others; and we have little doubt some greatly improved varieties of our more useful field plants will be the result. Mr Shurreff mentions (*Gen. Jour.* 4<sup>th</sup> vol. i. p. 365.) that the variety of the Swedish turnip cultivated in East Lothian had, by judicious selection, the seeds of which seed was saved, been improved in nutritious value upwards of 300 per cent. Potatoes and Swedish turnips, Mr Shurreff says, "appear to be susceptible of further improvement by judicious selection, as well as the different grains so long cultivated in this country and which, in almost every instance, have become spurious. But whatever may be the degree of improvement of which the agricultural produce of the country is susceptible, by the propagation of genuine seeds of the best varieties of plants, one remarkable feature of such an improvement is, that it could be carried into effect without any additional investment of capital, or destruction of that already employed. It would require, in the first instance, only a slight degree of observation amongst practical farmers to select the best varieties, and afterwards a small exercise of patience in their propagation. The whole increase of produce obtained by such means would go to support the unagricultural part of the population; it would, in the first instance be clear gain to the occupier, and ultimately to the owners of land. The difference of produce, arising from sowing the seed of a good and a bad variety of a plant, is so great, that it does not seem inconsistent with probability to state, that the gross agricultural produce of the country might be augmented, in the course of a few years, through the agency of improved seeds, to the amount of seven per cent.; and as the farmer's home consumption of produce, by such means, would be increased nearly ten per cent. what an enormous fund this forms for maintaining the unagricultural part of the population, and augmenting the income of landholders!"

4558. *The facility of propagating genuine seeds*, will become manifest from a statement of my practice. In the spring of 1855, a vigorous wheat-plant, near the centre of a field, was marked out, which produced 68 ears, that yielded 9473 grains. These were dibbled in the autumn of the same year, the produce of the second and third seasons sown broadcast in the ordinary way, and the fourth harvest put me in possession of nearly thirty quarters of sound grain. In the spring of the year I planted a fine purple-top Swedish turnip, that yielded exclusively of the seeds picked by birds, and those lost in threshing and cleaning the produce, 100,500 grains, a number capable of furnishing plants for upwards of five imperial acres. One-fourth of an acre was sown with the produce in the end of July for a seed crop, part of which it is in contemplation to sow for the same purpose in July 1859. In short, if the produce of the turnip in question had been carefully cultivated to the utmost extent, the third year's produce of seed would have more than supplied the demand of Great Britain for a season.

4559. *Plants and animals are both organic bodies*, from the germs of whose fecundating organs proceed new races, which yield crops, and thus an extensive view of improving agriculture through the agency of genuine seeds embraces the propagation of live stock. Now however important the propagation of live stock may be, when considered by itself, yet, when viewed in connection with our agricultural system, embracing the cultivation and improvement of the herbage which support animals, as well as those plants, parts of which form the ingredients of human sustenance it becomes less imposing. The analogy existing between animal and vegetable life is known and acknowledged, and it may be noted, that the union of the male and female organs of different varieties of a plant, under favourable circumstances, produces a new race, which partakes of the qualities of both parents, and which is termed a hybrid. Now hybrid varieties of agricultural plants, when suffered to intermingle with the original kind, deteriorate their influence around them like cross-bred animals, unrestrained in their intercourse with the general herd, till the character of the stock becomes changed, and consequently deteriorated or improved. In either case, propagation from the best variety alone would be attended with good effect. The principles of propagating vegetable and animal life are nearly the same; but the propagation of vegetables must extend that of animals in importance, as much as the vegetable produce of the country surpasses that of animals. Indeed animals may justly be considered mere machines for converting our inferior herbage into nutriment of a different description; grasses and roots are the raw materials, butcher's meat the manufactured commodity.

4560. *The importance of selecting varieties of cultivated plants* has been ably pointed out by Mr Robinson, an eminent botanist and an experienced practical gardener. "By means of varieties," he says, "the produce of our gardens and fields are not only increased in a tenfold degree, but the quality of the produce is improved in a still greater proportion. In them we perceive the labour and sagacity of man triumphing over the sterility of unassisted nature, and succeeding in giving birth to a race of beings calculated to supply his wants in a manner that original spontaneity never could have done. The difference between varieties that have sprung from the same species lies along the different purposes, and the different soils, climates, and climates. Some, by reason of their robust nature, are winter vegetables; and others, by being early are spring vegetables; while some are in perfection in summer, and others in autumn. The fruit produced by some is fit to eat when pulled off the tree; while the fruit of others is valuable by reason of its keeping till that season, when Nature rests to recruit her strength. Thus, in edible plants and fruits, we are supplied with an agreeable change throughout the year, from a difference in varieties that have sprung from the same species. In the earlier ages of the world, no idea could have been entertained of the

excellence some varieties have attained over their originals. Who, upon viewing the wild cabbage that grows along our sea-coast, would ever imagine that cauliflower or broccoli would have been produced by the same? Or who would expect the well-formed apple of a pound's weight from the ragged plant in our hedge? Many instances might be noticed of original species that are entirely fit to be eaten by the beasts of the field, the varieties of which afford a nutritious and wholesome food for man. Upon comparing the original variety of the *Daucus Carota*, the *Pastinaca sativa*, and some others indigenous to our climate, with their varieties produced by culture, we are struck with their great inferiority and cannot help reflecting on the hapless condition of that hungry savage who first taught us their use; for nothing short of the greatest privation could ever have led to that discovery. Indeed nothing is more obvious upon comparing original species with their varieties produced by culture than that we, by means of the latter, enjoy a vegetable food far preferable to that of our forefathers; a circumstance from which it may be inferred that posterity is destined to enjoy a better than that which we do now. For although it is reasonable to believe that there exists a degree of excellence attainable by varieties over the species whence they have sprung, yet as that degree is unknown and as it is probably beyond the power of man, of cultivation, or of time, to determine the same, we are justified in regarding it as progressive, and in considering the production of a good variety as the sign or harbinger of a better.

4861. *The power of distinguishing varieties* and of forming some idea of their worth at sight, is an attainment much to be desired, because valuable varieties may sometimes appear to those who have it not in their power to prove them by trial; and if they have the probability is, that the means to be employed require more care, time, and attention than they are disposed to bestow on plants the merits of which are doubtful whereas were such persons capable of forming an estimate of the worth of varieties from their appearance, then would they use means for their preservation whenever their appearance was found to indicate superiority. That this is an attainment of considerable importance, will be readily allowed; yet, that it, in some cases, requires the most strict attention, appears from the circumstance of varieties being often valuable, though not conspicuously so. Let us suppose, for instance, that a field of wheat there exists a plant, a new variety having two more fertile joints in its spike and equal to the surrounding wheat in every other respect a man accustomed to make the most minute observations, would scarcely observe such a variety unless otherwise distinguished by some peculiar badge nor would any but a person versed in plants know that it was of superior value if placed before him. How many varieties answering this description may have existed and escaped observation which had they been observed, and carefully tested, and have proved an invaluable acquisition to commerce! The number of fertile joints in the spike of the wheat generally cultivated varies from eighteen to twenty-two and the inhabitants of Great Britain and Ireland amount to nearly the same number of millions therefore, as the wheat produced in those islands has been of late years sufficient, or nearly sufficient, to supply the inhabitants thereof with bread it is evident that a variety with two additional fertile joints, and equal in other respects to the varieties at present in cultivation would, when it became an object of general culture, afford a supply of bread to at least two millions of souls, without even another ear being brought into cultivation, or one additional drop of sweat from the brow of the husbandman.

4862. *The same varieties are not repeatedly produced by culture*; if they were there would not exist that necessity for strict observation and skill on the part of observers because if a variety were lost or destroyed, we might look forward to its re-appearance or did we possess the power of producing varieties, and of producing them late or early, tall or dwarf, sweet or sour or just as we might wish to have them then might we plead an excuse for inattention. But experience shows, that when a variety is lost, it is for ever lost; and the slightest reflection cannot fail of convincing us that our power of producing them is most limited. Indeed our knowledge only enables us to produce those of the intermediate kind while varieties that confer extension or excellence are as likely to be produced from the seed sown and treated by the humble labourer as from that sown and treated by the ablest horticulturist, the most skillful botanist, or most profound philosopher of the age. From these remarks it is obvious, that the benefits mankind derive from the varieties produced by culture are numerous and important, and that the discovery of those of merit is an object highly deserving of our attention. (*Bishop's Ceresal Botany*.)

4863. *The varieties of wheat and barley in general cultivation*, Mr. Gorrie observes, are "not numerous, but were a part of that attention paid to the production of new and improved varieties of field-barley, pease, oats, beans, and wheat, which is now almost wasted on live-stock, the same success might follow and varieties of each of these useful species of grain might be found as far surpassing those now in cultivation as the modern breeds of horses and cattle surpass those of former days. To effect this a simple process only is necessary. When any two varieties are intended to be used in crossing it is necessary that they should be sown at such periods as may render them likely to flower at the same time and we would recommend that such plants should be sown or transplanted into flower pots, particularly the variety to be used as the *female breeder*. The parts of fructification of all the *Cerealia* tribe are composed of a stigma, or fringed substance which crowns the embryo grain, three anthers or male parts which have either a purple or yellow colour and form small, round, or rather longish cylindrical knobs with a hollow line longitudinally along the middle on the side farthest from the filament which supports these anthers. Allowing that there are six plants, say of wheat, in a pot to be impregnated let the variety possessing the greatest proportion of desirable qualities be selected for the *male* from a field or otherwise, and, before the anthers appear outside the glumes, let the chaff be opened by a slight touch of the forefinger, cut off the anthers of all the ears growing on the plants in the pot, and then take the male parts of the variety *calculated to be improved*, which have been newly out of the chaff and, before the farina is all dispersed touch the stigma of all the embryo grains whence the anthers have been previously removed gently with newly burst anthers, till the stigma is partially covered with the dust or pollen; keep the plants at a distance from the fields where grain of the same sort is coming in the flower till the flowering season is fairly over; then, to prevent sparrows or other birds from picking the impregnated grains, plunge the pots to the brims in a field of the same kind of grain. Save every seed and sow them carefully next season. If the process has been properly performed there may be many varieties even from one ear the best should be marked, and the produce of each stalk worthy of notice kept, and propagated *distinctly by itself*. If all the farmers in a district were to submit five or six plants only to such process, we might soon have hundreds of new varieties, and it is certainly within the limits of probability to expect a few varieties superior to any now in cultivation. (*Forth Miscellany* vol. i. p. 17.)

4864. *Grain, seeds, and roots intended for reproduction* are not required to have come to the same degree of maturity on the plant, as when intended for meal or other products to be consumed as food. The cause of this has never been satisfactorily explained; all that is alleged being the conjecture, that the ocydations of the seed are better fitted for entering the vessels of the minute plant, when they are not of a ferments nature, as when these ocydations are more mature. "That grain not perfectly matured is fully qualified for seed, is evident from places situated near rivers or lakes, where the grain in some seasons is subject to be what the people who cultivate such situations term *blasted* or *wilddened*. This happens in autumn, before the grain is matured, and is probably caused by fogs or damps which arise from the water. This *blast* discolors the straw and renders it so friable that it will hardly bind itself; the grain never receives any more nourishment, is shrivelled and light, and soon assumes a ripe appearance, and so small a quantity of glutinous matter will be contained in the grains, that a sheaf, after being reaped will feel as light in the hand as if it had been previously threshed; and yet, for as bad as it appears, it is commonly sown for seed, and never fails to give a luxuriant crop, provided it escape the following autumn." (*Ibid.*)

4865. *Of the plants which the farmer has to choose for stock, the chief is the potato; and every one knows that no circumstances in the soil, climate, or culture will compensate for planting a bad sort. The potato requires a climate rather humid than otherwise, and rather moderate and equable in temperature than hot; hence the best crops are found in Lancashire, Dumfriesshire, and Ayrshire in Britain, and in Ireland, where the climate is every where moist. Excellently flavoured potatoes are also grown on mossy lands in most parts of the country. The prudent farmer will be particularly careful in choosing this description of plant stock, and also in changing it frequently so as to ensure prolificacy and flavour. The general result of experience is decidedly in favour of upright tubers for the purpose of propagation. A number of important papers on this subject will be found in the first and second volumes of the *Gardener's Magazine*, all confirmatory of the advantages of selecting tubers which are immature.*

#### SECT. III. *Choice of Servants.*

4866. *On the moral and professional character of his servants much of the comfort of the farmer depends; and every one who has farmed near large towns, and at a distance from them, knows how great the difference is in every description of labourers. The servants required in farmeries are, the bailiff or head ploughman, common ploughmen, shepherds, labourers of all-work, herdsmen, and women. Sometimes apprentices and pupils are taken, but their labour is not often to be much depended on.*

4867. *A bailiff is required only in the largest description of farms, occupied by a professional farmer and is not often required to act as market-man. In general young men are preferred, who look forward to higher situations, as gentlemen's bailiffs or land stewards. Most farmers require only a head ploughman, who works the best pair of horses, and takes the lead of, and sets the example to, the other ploughmen in every description of work.*

4868. *Ploughmen should, if possible, be yearly servants, and reside upon the farm. If married, cottages should be provided for them. Weekly or occasional ploughmen are found comparatively unsteady; they are continually wandering from one master to another and are very precarious supports of a tillage farm, for they may quit their service at the most inconvenient time, unless bribed by higher wages, and the farmer may thus lose the benefit of the finest part of the season. Where ploughmen and day labourers, however, are married, they are more to be depended upon than unmarried domestic servants, more especially when the labourer has a family which ties him down to regular industry.*

4869. *The mode of hiring servants at what are called public statutes, so general in many parts of England, is justly reprobated as having a tendency to vitiate their minds, enabling them to get places without reference to character, exposing good servants to be corrupted by the bad, promoting dissipation, and causing a cessation of country business for some days, and an awkwardness in it for some time afterwards. When hiring servants, it would be extremely important, if possible, to get rid of any injurious perquisites, which are often prejudicial to the interests of the master without being of any advantage to the servant. For instance, in Yorkshire and in other districts it is a custom to give farm servants liquor both morning and evening, whatever is the nature and urgency of the work. Nothing can be more absurd than permitting a ploughman to stop for half an hour in a winter day to drink ale while his horses are neglected and shivering with cold.*

4870. *The following plan of maintaining the lands or ploughmen in the best cultivated districts in Scotland, is found by experience to be greatly superior to any other mode hitherto adopted.*

4871. *Proper houses are built for the farm servants contiguous to every farmstead. This gives them an opportunity of settling in life, and greatly tends to promote their future welfare. Thus also the farmer has his people at all times within reach for carrying on his business.*

4872. *The farm servants, when married, receive the greater part of their wages in the produce of the soil, which gives them an interest in the prosperity of the concern in which they are employed, and in a manner obliges them to eat and drink comfortably, while young men often starve themselves in order to save money for drinking or clothes, in either of which cases they are deficient in the requisite animal strength. At least under this mode of payment they are certain of being supplied with the necessities of life, and a rise of prices does not affect them, whereas when their wages are paid in money they are exposed to many temptations of spending it which their circumstances can ill afford, and during a rise of prices they are sometimes seized to considerable difficulties. From the adoption of an opposite system habits of sobriety and economy so conspicuous among the farm servants of Scotland, and the advantages of which cannot be too highly appreciated, have arisen and still prevail in these districts.*

4873. *A most important branch of this system is, that almost every married man has a cow of a moderate size kept for him by the farmer all the year round. This is a boon of great utility to his family. The prospect of enjoying this advantage has an excellent effect upon the morals of young unmarried servants, who in general make it a point to lay up as much of their yearly wages as will enable them to purchase a cow and furniture for a home when they enter into the married state. These savings, under different circumstances, would most probably have been spent in dissipation.*

4874. *They have also several other perquisites as a piece of ground for potatoes and fax (about one-eighth part of an acre for each); liberty to keep a pig, half a dozen hens, and here their fuel is carried home to them; they receive a small allowance in money per journey when sent from home with cows, or for oxen or lime; and during the harvest they are maintained by the farmer that they may be always at hand.*

4875. *There are nowhere to be met with more active, respectable, and conscientious servants than those who are best according to this system. There is hardly an instance of their soliciting relief from the public. They rear numerous families, who are trained to industry and knowledge in the operations of agriculture, and whose assistance in weeding the crops, &c. is of considerable service to the farmer. They become attached to the farm, take an interest in its prosperity and seldom think of running from it. Under this system every great farm is a species of little colony, of which the farmer is the resident governor. Nor on the whole, can there be a more gratifying spectacle than to see a large estate under the direction of an intelligent landlord, or of an agent competent to the task of managing it to advantage; where the farms are of a proper size where they are occupied by industrious and skilful tenants, anxious to promote in consequence of the lease, the improvement of the land in their possession and where the cultivation is carried on by a number of married servants enjoying a fair competence and rearing large families, sufficient not only to replace themselves, but also, from their surplus population to supply the demand and even the waste of the other industrious classes of the community. Such a system, there is reason to believe is brought to a higher degree of perfection and carried to a greater extent in the more improved districts of Scotland than perhaps in any other country in Europe. (Code &c.)*

4876. *A shepherd is of course only requisite on sheep farms and no description of farm servant is required to be so steady and attentive. At the lambing season much of the farmer's property is in his hands, and depends on his unwearied exertions early and late. Such servants should be well paid and comfortably treated.*

4877. *The labourers required on a farm are few in general one for field operations, as hedge and ditch work roads, the garden, cleaning out furrows, &c., and another for attending to the cattle, pigs, and straw yard, killing sheep and pigs when required, &c. will be sufficient. Both will assist in harvest, hay time threshing filling dung, &c. These men are much better servants when married and hired by the year, than when accidental day labourers.*

4878. *The female servants required in a farmery are casual as haymakers, turnip hoers, &c. or yearly as house dairy and poultry maids. Much depends on the steadiness of the first class, and it is in general better to select them from the families of the married servants, by which means their conduct and conversation is observable by their parents and relations. A skilful dairy maid is a most valuable servant, and it is well when the cattle-keeper is her husband both may live in the farmer's house (provided they have no children, and the man may act as groom to the master's horse and chaise, and assist in brewing, butchery &c. In the cheese districts, men often milk the cows, and manage the whole process of the dairy but females are surely much better calculated for a business of so domestic a nature, and where so much depends on cleanliness.*

4879. *Farmer's apprentices are not common but parish boys are so disposed of in some parts of the west of England and might be so generally. They are said to make the best and steadiest servants and indeed the remaining in one situation, and under one good master for a fixed period, say not less than three years, must have a great tendency to fix the character and morals of youth in every line or condition of life.*

4880. *Apprentices intended for farmers are generally young men who have received a tolerable education beforehand and have attained to manhood or nearly so. These pay a premium, and are regularly instructed in the operations of farming. We have already alluded to the example of Walker, who converts such apprentices, notwithstanding the care required to instruct them, rather useful than otherwise. (Hurd's Essay vol. ii. p. 106.)*

4881. *To train ploughmen to habits of activity and diligence is of great importance. In some districts they are proverbial for the slowness of their step, which they teach their horses whereas these animals, if accustomed to it, would move with as much ease to themselves in a quick as in a slow pace. Hence their ploughs seldom go above two miles in an hour and sometimes even less whereas, where the soil is light and sandy they might go at the rate of three miles and a half. Farmers are greater sufferers than they imagine by this habitual indolence of their workmen, which extends from the plough to all their other employments, for it makes a very important difference in the expense of labour (Code.)*

#### CHAP. IV

##### General Management of a Farm.

4882. *The importance of an orderly systematic mode of managing every concern is sufficiently obvious. The points which chiefly demand a farmer's attention are the accounts of money transactions, the management of servants, and the regulation of labour.*

##### SECT. I. Keeping Accounts.

4883. *It is a maxim of the Dutch, that "no one is ever ruined who keeps good accounts," which are said in The Code of Agriculture to be not so common among farmers as they ought to be, persons employed in other professions being generally much more attentive and correct. Among gentlemen farmers there is often a systematic regularity in all their proceedings, and their pages of debtor and creditor of expense and profit, are as strictly kept as those of any banking-house in the metropolis. But with the generality of farmers the case is widely different. It rarely happens that books are kept by*

4896 These forms may be useful by directing the attention of farmers to the particulars of which they should keep an accurate record but as to any particular system of accounts applicable to farmers a good deal of delusion seems to prevail, as if the established modes in general use among mercantile men would not answer. In fact, there is no correct mode of keeping accounts but by the principles of double entry.

4897 The account books for a common farmer may be, a cash-book for all receipts and payments, specifying each a ledger for accounts with dealers and tradesmen and a stock book for taking, once a year, an inventory and valuation of stock, crop, manures, tillages, and every thing that a tenant could dispose of or be paid for on quitting his farm. Farming may be carried on with the greatest accuracy and safety, as to money matters, by means of the above books, and a few pocket memorandum books for labourers time, jobs, &c. With the exception of a time-book, such as we have before described (3983), we should never require more, even from a proprietor's bailiff many of whom the nine forms just given (4887) would only puzzle, and some we have known them lead to the greatest errors and confusion. Munro's *Guide to Farm Book-keeping* (Edin. 18mo. 1821) may be recommended to the practical farmer but no form of books, or mode of procedure will enable a farmer to know whether he is losing or gaining but that of taking stock.

4898 A form for a cattle stock account has been recommended by Sir Patrick Murray of which it may be useful to present a specimen. This form, Sir Patrick observes, has been kept at his estate of Ochertyre, in Perthshire, for twenty-two years, and found perfectly adapted to the purpose in view being sufficiently simple in form to be understood by every farm manager, and sufficiently comprehensive in particulars to embrace all the requisite details. They may be either made up quarterly, half-yearly, or yearly. Sir Patrick adopts the half yearly mode.

### BOOK II. *Management of Servants.*

4900. *In former times, farm servants lived at the same table with their masters, and that is still the practice in those districts where the farms are small. On moderate-sized, and on large farms, they are usually sent to a separate table; but of late a custom has been introduced of putting them on board-wages. This is a most pernicious practice, which often leads them to the ale-house, corrupts their morals, and injures their health. It is a better plan, with a view of lessening trouble, to board them with the bailiff, but it is still more desirable for the farmer to have them under his own eye, that he may attend to their moral conduct. He will find much more useful assistance from the decent and the orderly than from the idle and the prodigal.*

4901. *The best mode of managing yearly married servants, whether ploughmen or labourers, we conceive to be that already referred to (4870) as practised in Northumberland, and other northern counties. Marshall (*Review of Bailey's Northumberland*) calls it a remnant of feudal times, but certainly if it be so, it appears one of those remnants which should be carefully preserved. We may challenge the empire to produce servants and farm operations equal to those where this system is adopted. The great excellence of the system consists on its being founded in the comfort of the servant.*

4902. *The permanent labourers on a farm ought to be treated in the same manner as the ploughmen, and indeed it is much to be wished, for the sake both of humanity and morality, that all married labourers, who live in the country should have gardens attached to their cottages, if not a cow kept, and a pig and fowls, in the manner of the Scottish ploughmen. Some valuable observations on this subject will be found in *The Husbandry of Scotland*.*

4903. *Temporary labourers, or such as are engaged for hay-making, reaping, turnip-hoeing, &c. are for the most part beyond the control of the farmer as to their living and lodging. It is a good practice, however, where hay making and reaping are performed by the day to feed the operators, and to lodge on the premises such of them as have not homes in the neighbourhood, providing them with a dry loft and warm blankets. Piece or job-work, however is now becoming so very general, in all farm operations performed by occasional labourers, that attention to these particulars becomes unnecessary, and the farmer's chief business is to see that the work be properly done.*

4904. *A day's work of a country labourer, is ten hours during the spring, summer and autumn quarters. Farmers, however are not at all uniform in their hours of working during these periods. Some begin at five o'clock, rest three hours at mid-day during the more violent heat of the sun, and fill up their day's work by beginning again at one o'clock, and ending at six in the evening. Others begin at six, and end at six allowing half an hour at breakfast, and an hour at dinner. But although these are the ordinary hours, both for servants and labourers, during the more busy seasons of the year, yet neither of them will scruple to work either sooner or later when occasion requires. In regard to the winter months, the hours of labour are from the dawn of morning, as long as it is light, with the allowance of about half an hour at mid-day for dinner.*

4905. *That the rate of labour must in a great measure depend upon the price of grain, is a general principle. In England, the value of a peck of wheat, and in Scotland, of a peck of oatmeal (being the principal articles of subsistence of the lower orders of the people in the two countries), were long accounted an equivalent to the daily pay of a labourer. In both countries, however, the price of potatoes has, of late years, had a considerable influence on the rate of labour, and in England, the effects of the poor laws have tended to keep down that rate below the increased price of provisions, and thus have deranged the natural progress of things. It has been ascertained, that a man, his wife, and from two to three children, if wheat is their habitual food, will require ten gallons weekly. When they live on bread, hard-working people ought to have the best kind, as that will furnish the most nutrition. How, then, could a labourer and his family exist upon wages of from 6s. to 9s. per week, when wheat is from 8s. to 10s. or 12s. per bushel? The difference is compensated by the poor-rates, a most exceptionable mode of making up the deficiency for labour would otherwise have found its own level, and the labourer would have obtained the price of a bushel and a half of wheat weekly.*

4906. *In Scotland, the rate of labour has increased beyond the price of provisions. Prior to 1788, the average price of a peck of oatmeal was 1s. 1d. and the average price of a day's labour in summer is 1s. 4d., which nearly corresponded with the principle above stated, but the average price of a peck of oatmeal in 1810 was 1s. 3d., whilst the average price of a day's labour was 1s. 10d., which shows, in a most satisfactory manner, the very great improvement that has taken place in the lot of the labouring classes in that part of the United Kingdom. (*Gen. Rep. vol. in p. 285.*)*

4907. *The practice of giving labourers grain, &c. at a cheap rate was adopted by George III. who carried on farming operations to a considerable extent, allowing his labourers flour at a fixed price, whatever wheat might sell for. This benevolent system has been practised by several gentleman farmers, some of whom have allowed bread, and others a daily quantity of milk, at moderate prices. The same system is general in several of the western counties, as in Dorset, Devon, and Cornwall, where the labourers have a standing supply of bread-corn of wheat at 6s. and of barley at 5s. per bushel. In some of the midland*

contains the day-wages are regulated by the price of the best wheaten bread: thus the price of a half-peck loaf fixes the day-wages for out-of-door farm servants. Of late years this rule has been departed from in favour of the labourers: thus, when bread is at 1s. 6d. the half-peck, then wages are 1s. 30d.; and when at 8s. the wagon are 2s. 4d.

4908. *Most descriptions of country labour*, performed without the aid of horses, may be let by the job. Farcy in his excellent *Report of Derbyshire*, informs us, that besides all ordinary labour, the late John Billingsley of Ashwick Grove, in Somersetshire, let his ploughing, harrowing, rolling, sowing, turning of corn when cut, hay-making, &c. by the acre; from which he found great advantages, even where his own oxen and horses were used by the takers of the work. Whether we regard despatch, economy, perfection of rural works, or the bettering of the condition of the labourers therein, nothing will contribute so much to all these as a general system of letting works at fair and truly apportioned prices, according to the degree of labour and skill required in each kind of work. Few persons have doubted that despatch and economy are attainable by this method, but those who have indolently or improperly gone about the letting of their labour, have uniformly complained of its being slovenly done, and of the proneness of the men to cheat when so employed. Such frauds are to be expected in all modes of employment, and can only be counteracted, or made to disappear by competent knowledge and due vigilance in the employer, or his agents and foremen, who ought to study and understand the time and degree of exertion and skill as well as the best methods, in all their minutiae, of performing the various works they have to let. At first sight these might seem to be very difficult and unattainable qualifications in farmers' bailiffs or foremen, but it is nevertheless certain, that a proper system and perseverance will soon overcome these difficulties. One of the first requisites is, the keeping of accurate and methodical day-accounts of all men employed and, on the measuring up and calculating of every job of work, to register how much has been earned per day and never to attempt abatement of the amount, should this even greatly exceed the ordinary day's pay of the country: but let this experience gained operate in fixing the price of the next job of the same work, in order to lessen the earnings by degrees, of fully competent and industrious men, to  $1\frac{1}{2}$  or  $1\frac{3}{4}$  times the ordinary wages when working by the day.

4909. *Form the men into small gangs*, according to their abilities and industry and always set the best gang about any new kind of work, or one whose prices want regulating: encourage these by liberal prices at first, gradually lowering them and by degrees introduce the other gangs to work with or near them at the same kind of work. On the discovery of any material slight of or deception in the work, at the time of measuring it, more than their proportionate values should be deducted for them, and a separate job made to one of the best gangs of men for completing or altering it: by which means shame is made to operate, with loss of earnings, in favour of greater skill, attention and honesty in future. When the necessity occurs of employing even the best men by the day let the periods be as short as possible, and the prices considerably below job savings: and contrive, by the offer of a desirable job so follow to make it their interest and wish to despatch the work that is necessary to be done by the day, in order to get again to piece-work. The men being thus induced to study and contrive the readiest and best methods of performing every part of their labour and of expending their time, the work will unquestionably be better done than by the thoughtless drones who usually work by the day. And that these are the true methods of bettering the condition of the labourers, Malthus has ably shown in theory; and all those who have adopted and persevered in them have seen the same in practice. (*Farcy's Derbyshire* vol. iii. 198.)

### SECT. III. Arrangement of Farm Labour.

4910. *The importance of order and system* we have already insisted on (3970), and the subject can hardly be too often repeated. To conduct an extensive farm well is not a matter of trivial moment, or one to the management of which every man is competent. Much may be effected by capital, skill, and industry: but even these will not always ensure success without judicious arrangement. With it, a farm furnishes an uninterrupted succession of useful labour during all the seasons of the year and the most is made that circumstances will admit of, by regularly employing the labouring persons and cattle, at such works as are likely to be the most profitable. Under such a system it is hardly to be credited how little time is lost, either of the men or horses, in the course of a whole year. This is a great object for each horse may be estimated at three shillings per day, and each man at two shillings. Every day, therefore, in which a man and horse are unemployed occasions the loss of at least five shillings to the husbandman.

4911. *As the foundation of a proper arrangement*, it is necessary to have a plan of the farm, or at least a list of the fields or parcels of land into which it is divided, describing their productive extent, the quality of the soil, the preceding crops, the cultivation given to each, and the species and quantity of manure they have severally received. The future treatment of each field, for a succession of years, may then be resolved on with more probability of success. With the assistance of such a statement, every autumn an arrangement of crops for the ensuing year ought to be made out: cleaning the fields or pieces of land, according to the purposes for which they are respectively intended. The number of acres allotted for stubble land, meadow, or pasture, will thus be ascertained. It will not then be difficult to discover what number of horses and labourers will be

required during the season for the fields in culture, nor the live stock that will be necessary for the pasture land. The works of summer and harvest will likewise be foreseen, and proper hands engaged in due time to perform them.

4912. *A farmer should have constantly in view a judicious rotation of crops, according to the nature and quality of his soil, and should arrange the quantity and succession of labour accordingly.* Team labour, when frost and bad weather do not intervene, should be arranged for some months, and hand labour, for some weeks, according to the season of the year. "A general memorandum list of business to be done," may therefore be useful, that nothing may escape the memory, and that the most requisite work may be brought forward first, if suitable to the state of the weather. In this way the labour will go on regularly and without confusion while, by a proper attention, either a distribution of labour or an occasional consolidation of it, may be applied to every part of the farm.

4913. *As general rules, connected with the arrangement, and the successful management of a farm, the following are particularly to be recommended* —

4914. *The farmer ought to rise early and see that others do so. In the winter season breakfast should be taken by candle-light, for by this means an hour is gained which many farmers unduly lose though six hours in a week are nearly equal to the working part of a winter day. This is a material object, where a number of servants are employed. It is also particularly necessary for farmers to insist on the punctual performance of their orders.*

4915. *The whole farm should be regularly inspected and not only every field examined, but every beast seen, at least once a day either by the occupier or by some intelligent servant.*

4916. *In a considerable farm, it is of the utmost consequence to have servants specially appropriated for each of the most important departments of labour, for there is often a great loss of time where persons are frequently changing their employments. Besides, where the division of labour is introduced, work is executed not only more expeditious, but also much better in consequence of the same hands being constantly employed in one particular department. For that purpose, the ploughmen ought never to be employed in manual labour but regularly kept at work with their horses, when the weather will admit of it.*

4917. *To arrange the operation of ploughing according to the soils cultivated is an object of essential importance. On many farms there are fields which are soon rendered unfit to be ploughed either by much rain or by severe drought. In such cases, the prudent farmer before the wet season commences, should plough such land as is in the greatest danger of being injured by too much wet, and before the dry period of the year sets in, he should till such land as is in the greatest danger of being rendered unfit for ploughing by too much drought. The season between seed-time and winter may be well occupied in working soils intended to be sown with beans, oats barley and other spring crops. On farms where these rules are attended to there is always some land in a proper condition to be ploughed, or to be worked by the improved harrows or grubbers and there is never any necessity either for delaying the work, or performing it improperly.*

4918. *Every means should be thought of to diminish labour or to increase its power. For instance, by proper arrangement, five horses may do as much labour as six perform, according to the usual mode of employing them. One horse may be employed in carting turnips during winter, or in other necessary farm work at other seasons, without the necessity of reducing the number of ploughs. When drying dung from the farm-yard, three carts may be used, one always filling in the yard another going to the field, and a third returning the leading horse of the empty cart ought then to be unyoked and put to the full one. In the same manner, while one pair of horses are preparing the land for sowing turnips, the other three horses may be employed in carrying the dung to the land either with two or three carts, as the situation of the ground may happen to require. By attending the same management to other farm operations, a considerable saving of labour may be effected.*

4919. *Freedom in engaging in a work whether of ordinary practice, or of intended improvement the best consideration of which the farmer is capable ought to be given to it, till he is satisfied that it is advisable for him to attempt it. When begun he ought to proceed on it with much attention and perseverance until he has given it a fair trial. It is a main object, in carrying on improvements, not to attempt too much at once and never to begin a work without a probability of being able to finish it in due season.*

4920. *By the adoption of these rules every farmer will be master of his time, so that every thing required to be done will be performed at the proper moment, and not delayed till the season and opportunity have been lost. The impediments arising from bad weather sick servants, or the occasional and necessary absence of the master will in that case, be of little consequence nor will they embarrass the operations to be carried on and the occupier will not be prevented from attending to even the smallest concerns connected with his business, on the aggregate of which his prosperity depends.*

#### SECT IV Domestic Management and personal Expenses

4921. *On domestic affairs a hint may suffice. Young farmers beginning house-keeping, like most others in similar circumstances, are apt to sink too great a proportion of their capital in furniture and furnishing riding-horses carriages, &c. and sometimes to live up to, or even beyond, their income. We do not mean that farmers should not live as well as other men of the same property but merely that all beginners should live within their income. Even in the marketing expenses care is requisite, and the prudent farmer will do well, every penny or expence he lays out, to reckon up in his mind what that sum per day would amount to in a year. The amount will often astonish him and lead to economy and, where practicable, retrenchment. Saving, as Franklin has inculcated, is the only certain way of accumulating money.*

4922. *In regard to housekeeping, it is observed in The Code of Agriculture, that the safest plan is, not to suffer it to exceed a certain sum for bought articles weekly. An annual sum should be allotted for clothing, and the personal expenses of the farmer, his*

wife and children, which ought not to be exceeded. The whole allotted expenses should be consistently within the probable receipts; and, if possible, one eighth of the income annually received should be laid up for contingencies, or expended in extra improvements on the farm.

## BOOK VI

### CULTURE OF FARM LANDS.

4923. *The business of farming* consists of the culture of vegetables, and the treatment or culture of animals in practice these are generally carried on together, but may be more conveniently treated of apart. In this Book, therefore, we confine ourselves to the culture of vegetables, and shall consider in succession the general processes of culture, the culture of corn and pulse; of roots and leaves, of herbage plants, of grasses, and of manufactory plants.

## CHAP. I.

### General Processes common to Farm Lands.

4924. *Among general processes*, those which merit particular notice in this place are, the rotation of crops, the working of fallows, and the management of manures. The theory of these processes has been already given in treating of soils and manures (PART II. Book III.) and it therefore only remains to detail their application to practice under different circumstances.

#### SECT. I. Rotation of Crops suitable to different Descriptions of Soils.

4925. *The proper distribution of crops, and a plan for their succession*, is one of the first subjects to which a farmer newly entered on a farm requires to direct his attention. The kind of crops to be raised are determined in a great measure by the climate, soil and demand, and the quantity of each by the value, demand, and the adjustment of farm labour.

4926. *In the adjustment of farm labour*, the great art is to divide it as equally as possible throughout the year. Thus it would not answer in any situation to sow exclusively autumn crops, as wheat or rye nor only spring crops, as oats or barley for by so doing all the labour of seed-time would come on at once, and the same of harvest work, while the rest of the year there would be little to do on the farm. But by sowing a portion of each of these and other crops, the labour both of seed-time and harvest is divided and rendered easier, and is more likely to be done well and in season. But this point is so obvious as not to require elucidation.

4927. *The succession or rotation of crops* is a point on which the profits of the farmer depend more than on any other. It is remarked by Arthur Young, that agricultural writers, previously to the middle of the eighteenth century paid little or no attention to it. They recte, he says, courses good, bad, and execrable in the same tone, as matters not open to praise or censure, and unconnected with any principles that could throw light on the arrangement of fields. The first writer who assigned due importance to the subject of rotations seems to have been the Rev. Adam Dickson, in his *Treatise on Agriculture* published in Edinburgh in 1777 and soon afterwards Lord Kaimes, in his *Gentleman Farmer*, illustrates the importance of the subject both writers were probably led to it by observing the effects of the Norfolk husbandry, then beginning to be introduced to Warwickshire. But whatever may have been the little attention paid to this subject by former writers, the importance of the subject of rotations, and the rule founded on the principles already laid down, that calumiferous crops ripening their seeds should not be repeated without the intervention of pulse, roots, herbage, or fallow, is now "recognised in the practice and writings of all judicious cultivators, more generally perhaps than any other" (*Edin. of Farmer's Mag.*)

4928. *The system of rotations is adapted for every soil*, though no particular rotation can be given for any one soil which will answer in all cases; as something depends on climate, and something also on the kind of produce for which there is the greatest market demand. But wherever the system of rotations is followed, and the several processes of tillage which belong to it properly executed, land will rarely get into a foul and exhausted state, or at least, if foul and exhausted under a judicious rotation, "restoration would be much easier were any other system followed."

4929. *The particular crops which enter into a system of rotation must obviously be such as are suited to the soil and climate*, though, as the experienced author so often quoted observes, "they will be somewhat varied by local circumstances, such as the proximity of towns and villages, where there is a greater demand for turnips, potatoes, hay &c. than in thinly peopled districts. In general, beans and clover, a high dry grass, are interspersed between corn crops on clayey soils; and turnips, potatoes, and clover with red grass on dry loams and sands, or what are technically known by the name of turnip soils. A variety of

other plants, such as peas, turneps, cabbages, and carrots, occupy a part, though commonly but a small part, of that division of a farm which is allotted to green crops. This order of succession is called the system of *alternate husbandry*; and on rich soils, or such as have access to abundance of potashy manure, it is certainly the most productive of all others, both for food for man and for the inferior animals. One half of a farm is in this course always under some of the different species of cereal grasses, and the other half under pulse roots, cultivated herbage, or plain fallow.

4930. *But the greater part of the arable land of Britain cannot be maintained in a fertile state under this management* and sandy soils, even though highly manured, soon become too incabere under a course of constant tillage. It therefore becomes necessary to leave that division or break that arrives cultivated herbage to be pastured for two years or more according to the degree of its consistency and fertility and all the fields of a farm are treated thus in their turn if they require it. This is called the system of *convertible husbandry* a regular change being constantly going on from aration to pasturage, and ever *verid*.

4931. *Not to repeat the same kind of crop at too short intervals* is another rule with regard to the succession of crops. Whatever may be the cause, whether it is to be sought for in the nature of the soil or of the plants themselves, experience clearly proves the advantages of introducing a diversity of species into every course of cropping. When land is pastured several years before it is brought again under the plough there may be less need for adhering steadily to this rule but the degeneracy of wheat and other corn crops recurring upon the same land every second year for a long period, has been very generally acknowledged. It is the same with what are called great crops beans and peas, potatoes, turnips, and in an especial manner red clover become all of them much less productive and much more liable to disease when they come into the course, upon the same land, every second, third, or fourth year. But what the interval ought to be has not yet been ascertained, and, from the great number of years that experiments must be continued to give any certain result, probably cannot be determined until the component parts of soils and particularly the sort of vegetable nourishment which each species of plant extracts from the soil, have been more fully investigated.

4932. *A change of variety as well as of the species, and even of the plants of the same variety is found to be attended with advantage* and in the latter case, or a change of seed, the species and variety being the same, the practice is almost universal. It is well known, that of two parcels of wheat, for instance, as much alike in quality as possible the one which had grown on a soil differing much from that on which it is to be sown, will yield a better produce than the other that grew in the same or a similar soil and climate. The farmers of Scotland accordingly find that wheat from the south even though it be not, as it usually is better than their own is a very advantageous change and oats and other grain brought from a clayey to a sandy soil other things being equal, are more productive than such as have grown on sandy soil. (Supp. Encyc. Brit art. Agr 164.)

4933. *The following are examples of rotations suited to different soils as given in Brown's excellent Treatise on Rural Affairs.* The basis of every rotation, he says, we hold to be either a bare summer fallow or a fallow on which drilled turnips are cultivated, and its conclusion to be with the crops taken in the year preceding a return of fallow or drilled turnips, when of course a new rotation commences.

4934. *Rotation for strong deep lands.* According to this rotation wheat and drilled beans are the crops to be cultivated, though clover and rye grass may be taken for one year in place of beans, should such a variety be viewed as more eligible. The rotation begins with summer fallow, because it is only on strong deep lands that it can be profitably practised and it may go on for any length of time, or so long as the land can be kept clean, though it ought to stop the moment that the land gets into a contrary condition. A considerable quantity of manure is required to go on successfully perhaps dung should be given to each bean crop and if this crop is drilled and attentively horse-hoed the rotation may turn out to be one of the most profitable that can be exercised.

4935. *Rotation for loams and clays.* Where it may not be advisable to carry the first rotation into execution a different one can be practised, according to which labour will be more divided, and the usual grasses more generally cultivated. For instance, the following, which used to be common in East Lothian —

- |                                   |                          |                                  |
|-----------------------------------|--------------------------|----------------------------------|
| 1. Fallow with dung.              | 4. Barley                | 7. Beans drilled and horse-hoed. |
| 2. Wheat.                         | 5. Clover and rye-grass. | 8. Wheat.                        |
| 3. Beans, drilled and horse-hoed. | 6. Oats or wheat.        |                                  |

The rotation is excellently calculated to insure an abundant return through the whole of it, provided dung is bestowed upon the clover stubble. Without this supply the rotation would be crippled, and inferior crops of course produced in the concluding years.

4936. *Rotation for clays and loams of an inferior description.* This rotation is calculated for soils of an inferior description to those already treated of.

- |                     |                          |                                   |
|---------------------|--------------------------|-----------------------------------|
| 1. Fallow with dung | 3. Clover and rye-grass. | 5. Beans, drilled and horse-hoed. |
| 2. Wheat.           | 4. Oats.                 | 6. Wheat.                         |

According to this rotation, also in use in East Lothian, the rules of good husbandry are studiously practised while the sequence is obviously calculated to keep the land in good order and in such a position as to ensure crops of the greatest value. If manure is bestowed either upon the clover-stubble or before the beans are sown the rotation is one of the best that can be devised for the soil mentioned.

4937. *Rotation for this clay.* On thin clays gentle husbandry is indispensably necessary, otherwise the soil may be exhausted, and the produce unequal to the expense of cultivation. Soils of this description will not improve much while under grass but unless an additional stock of manure can be procured there is a necessity of refreshing them in that way, even though the produce should in the mean time be comparatively of small value. The following rotation is not an improper one —

- |                      |  |           |
|----------------------|--|-----------|
| 1. Fallow with dung. | 3. Grass pastured, but not too early eaten | 5. Grass. |
| 2. Wheat.            | 4. Grass.                                  | 6. Oats.  |

This rotation may be shortened or lengthened, according to circumstances, but should never extend further in point of ploughing than when dung can be given to the fallow break. This is the keystone of the whole and if neglected the rotation is rendered useless.

4938. *Rotation for poor earth soils.* These are not friendly to wheat, unless aided by a quantity of calcarious matter. Taking them in a general point of view it is not advisable to cultivate wheat, but a crop of oats may almost be depended upon provided the previous management has been judiciously executed. If the soil is of poor earth lands a mixture of moisture the process ought to commence with a bare summer fallow; but if such are incumbent on free and open bottoms a crop of turnips may be substituted for fallow; according to which method, the surface will get a body which naturally it did not possess. Grass on such soils must always occupy a great space of every rotation, because physical circumstances render regular cropping utterly impracticable.

- |                                  |                                    |  |
|----------------------------------|------------------------------------|--|
| 1. Fallow, or turnips with dung. | quantity of perennial rye-grass.   | circumstances permit the land to be broken up, when oats are to be repeated. |
| 2. Oats of an early variety      |                                    |  |
| 3. Clover and a considerable     | 4. Pasture for several years, till |  |

4393. *Rotation for light soils.* These are easily managed, though to procure a full return of the profit which they are capable of yielding, requires generally as much attention as is necessary in the management of those of a stronger description. Upon light soils, a bare summer fallow is seldom called for; at seasons may be preserved by growing turnips, and other leguminous articles. Grass also is of advantage upon such soils, often yielding a greater profit than what is afforded by culmiferous crops.

1. Turnips.

2. Spring wheat, or barley

3. Clover and rye-grass.

4. Oats or wheat.

This is a fashionable rotation; but it may be doubted whether a continuance of it for any considerable period is advisable, because both turnips and clover are found to fall off when repeated so often as once in four years. Common red clover will not grow every four years, unless gypsum be restored to the land. Perhaps the rotation would be greatly improved were it extended to eight years, whilst the ground, by such an extension, would be kept fresh and constantly in good condition. As, for instance, were seeds for pasture sown in the second year, the ground kept three years under grass, broke up for oats in the sixth year drilled with beans and peas in the seventh and sown with wheat in the eighth, the rotation would then be complete, because it included every branch of husbandry and admitted a variety in management generally agreeable to the soil, and always favourable to the interest of cultivators. The rotation may also consist of six crops, were the land kept only one year in grass, though few situations admit of so much cropping, unless additional manure is within reach.

4394. *Rotation for sandy soils.* These, when properly manured, are well adapted to turnips, though it rarely happens that wheat can be cultivated on them with advantage unless they are dressed with alluvial compost, marl, clay, or some such substances as will give a body or strength to them, which they do not naturally possess. Barley, oats, and rye, the latter especially so, however, or pure crops on made, and in favourable seasons will return greater profit than can be obtained from wheat.

1. Turnips well manured consumed on the ground.

2. Barley sown with clover and rye-grass

3. Clover and rye-grass.

4. Wheat, rye, or oats.

By keeping the land three years in grass, the rotation would be extended to six years, a measure highly advisable."

4391. *These examples are sufficient to illustrate the subject of improved rotations*—but as the best general schemes may be sometimes momentarily deviated from with advantage, the same able author adds, that "*cross cropping, in some cases, may perhaps be justifiable in practice*—as, for instance, we have seen wheat taken after oats with great success, when these oats had followed a clover crop on rich soil—but, after all as a general measure, that mode of cropping cannot be recommended. We have heard of another rotation, which comes almost under the like predicament, though, as the test of experience has not yet been applied a decisive opinion cannot be pronounced upon its merits. This rotation begins with a bare fallow and is carried on with wheat, grass for one year or more, oats, and wheat, where it ends. Its supporters maintain that beans are an uncertain crop, and cultivated at great expense and that in no other way will corn, in equal quantity and of equal value, be cultivated at so little expense as according to the plan mentioned. That the expense of cultivation is much lessened, we acknowledge, because no more than seven ploughings are given through the whole rotation but whether the crops will be of equal value, and whether the ground will be preserved in equally good condition are points which remain to be ascertained by experience." (*Brown on Rural Affairs.*)

4392. *As a general guide to devising rotations on clay soils,* it may be observed, that winter or autumn sown crops are to be preferred to such as are put in in spring. Spring ploughing on such soils is a hazardous business, and not to be practised where it can possibly be avoided. Except in the case of drilled beans, there is not the slightest necessity for ploughing clays in the spring months—but as land intended to carry beans ought to be early ploughed, so that the benefit of frost may be obtained, and as the seed furrow is an ebb one, rarely exceeding four inches in deepness, the hazard of spring ploughing for this article is not of much consequence. Ploughing with a view to clean soils of the description under consideration has little effect, unless given in the summer months. Thus renders summer fallow indispensably necessary and without this radical process, none of the heavy and wet soils can be suitably managed, or preserved in a good condition.

4393. *To adopt a judicious rotation of cropping for every soil,* requires a degree of judgment in the farmer, which can only be gathered from observation and experience. The old rotations were calculated to wear out the soil, and to render it unproductive. To take wheat, barley and oats in succession a practice very common thirty years ago, was sufficient to impoverish the best of land, while it put little into the pockets of the farmer; but the modern rotations, such as those which we have described, are founded on principles which secure a full return from the soil without lessening its value, or impoverishing its condition. Much depends however, upon the manner in which the different processes are executed, for the best arranged rotation may be of no avail, if the processes belonging to it are imperfectly and unseasonably executed. (See 2321.) The best farmers in the northern counties now avoid over-cropping or treading land in any way so as to exhaust its powers, as the greatest of all evils.

## SECT. II. The working of Fallows.

4394. *The practice of fallowing, as we have seen in our historical view of Greek and Roman agriculture, has existed from the earliest ages; and the theory of its beneficial*

affects we have endeavoured to explain. (2175.) The Romans with their agriculture introduced fallows in every part of Europe; and two crops, succeeded either by a year's fallow, or by leaving the land to rest for two or more years, became the rotation on all soils and under all circumstances. This mode of cultivating arable land is still the most universal in Europe, and was prevalent in Britain till the middle of the last century; but as a crop was lost every year they occurred, a powerful aversion from naked fallows arose about that time, and called forth numerous attempts to show that they were unnecessary and consequently an immense public loss. This anti-fallowing mania, as it has been called, was chiefly supported by Arthur Young, Nathaniel Kent, and others, members or correspondents of the Board of Agriculture: it was at its greatest height about the beginning of the present century, but has now spent its force; and after exhausting all the arguments on both sides, as an able author has observed, "the practice does not appear to give way, but rather to extend."

4945 *The expediency or inexpediency of pulverising and cleaning the soil by a bare fallow, is a question that can be determined only by experience, and not by argument. No reasons, however ingenious, for the omission of this practice, can bring conviction to the mind of a farmer, who, in spite of all his exertions, finds, at the end of six or eight years, that his land is full of weeds, sour, and comparatively unproductive. Drilled and horse-hoed green crops, though cultivated with advantage on almost every soil are probably in general unprofitable as a substitute for fallow, and after a time altogether inefficient. It is not because turnips, cabbages, &c. will not grow in such soils, that a fallow is resorted to, but because, taking a course of years, the value of the successive crops is found to be so much greater, even though an unproductive year is interposed, as to induce a preference to fallowing. Horse-hoed crops, of beans in particular, postpone the recurrence of fallow but in few situations can ever exclude it altogether. On the other hand, the instances that have been adduced, of a profitable succession of crops on soils of this description without the intervention of a fallow are so well authenticated, that it would be extremely rash to assert that it can in no case be dispensed with on clay soils. Instances of this kind are to be found in several parts of Young's *Annals of Agriculture*; and a very notable one, on Greg's farm of Coles, in Hertfordshire, is accurately detailed in the sixth volume of *The Communications to the Board of Agriculture*.*

4946 *The principal causes of this extraordinary difference among men of great experience may probably be found in the quality of the soil, or in the nature of the climate, or in both. Nothing is more vague than the names by which soils are known in different districts. Greg's farm, in particular though the soil is denominated "heavy arable land, and very heavy land, is found so suitable to turnips, that a sixth part of it is always under that crop, and these are consumed on the ground by sheep—a system of management which every farmer must know to be altogether impracticable on the wet tenacious clays of other districts. It may indeed be laid down as a criterion for determining the question, that wherever this management can be profitably adopted, fallow as a regular branch of the course, must be not less absurd than it is injurious, both to the cultivator and to the public. It is probable, therefore, that, in debating this point, the opposite parties are not agreed about the quality of the soil and, in particular about its propensity of absorbing and retaining moisture, so different in soils that in common language have the same denomination.*

4947 *Another cause of difference must be found in the climate. It is well known that a great deal more rain falls on the west than on the east coast of Britain—and that between the northern and southern counties there is at least a month or six weeks' difference in the maturation of the crops. Though the soil, therefore, be as nearly as possible similar in quality and surface, the period in which it is accessible to agricultural operations must vary accordingly. Thus in the south-eastern counties of the island, where the crops may be all out down, and almost all carried home by the end of August much may be done in cleaning and pulverising the soil, during the months of September and October, while the farmers of the north are exclusively employed in harvest work, which is frequently not finished by the beginning of November. In some districts in the south of England, wheat is rarely sown before December whereas in the north, and still more in Scotland, if it cannot be got completed by the end of October it must commonly be delayed till spring or oats or barley be taken in place of wheat. It does not then seem of any utility to enter farther into this controversy which every skilful cultivator must determine for himself. All the crops and all the modes of management which have been proposed as substitutes for fallow are well known to such men, and would unquestionably have been generally adopted long ago, if upon a careful consideration of the advantages and disadvantages on both sides, a bare fallow was found to be unprofitable in a course of years. The reader who wishes to examine the question fully may consult, among many others, the following—Young's *Annals of Agriculture* and his writings generally, Elphinstone's *Georgical Essays*; Duckson's *Practical Agriculture*; Sir H. Davy's *Agricultural Chemistry*; *The Agricultural Chemistry of Chaptal*; Brown's *Treatise on Rural Affairs*; *The County Reports*; *The General Report of Scotland*, and the *Quarterly Journal of Agriculture*, vol. II. p. 30.*

4948 *The importance of naked fallows has been ably pointed out by a writer in the work last referred to. In order," he says, "to show more forcibly the difficulty of cleaning heavy lands for green crops, let us take a review of the time of the year in which these crops should be sown. In clay lands, beans must be sown in March at latest, and before that period of the year no one can pretend to clean land at all. Finding it impossible to use them as a fallow crop, they are sown without dung on that part of the rotation which is penultimate to bare fallow. On light lands, beans will not carry much straw without manure, and their utility as a crop in the rotation is, of course, thereby much decreased on such soils, and if they are to be sown as a fallow crop with dung on the land that is to be appropriated to fallow they give much less time for the preparatory cleaning of the land than turnips, as they must be sown at latest in April. On all kinds of soil potatoes must be planted by April, and the same observations will, therefore, apply to them as to beans as a cleaner of the land. It is only from their great value as human food, and from their inability to grow without dung, that they are planted as a fallow crop because it is impracticable to keep land clean and much more so to make it clean, under a potato fallow. Thus there is difficulty in cleaning land, without summer fallows, with beans and potatoes on every kind of soil in any spring, however favourable and it is quite impossible to do so in a wet one. There is also difficulty in cleaning strong clay land even by turnip-time in May; and*

the greatest facility which a farmer possesses of cleaning his land or keeping it clean, under a green crop, is by a turnip row, or a light soil sowing on an open bottom, in a dry season. This has informed themselves, as fact, to all the limited possibility of keeping land clean by green crops, without the assistance of bare fallow. But even this substitution is only an approximation to cleanliness, for every one knows, who has turned light soils for a series of seasons, whatever his practice may be, that even the turnip crop cannot be relied on them for an indefinite period without the land getting foul with root-weeds, such as radishes and knot grass, and no better mode of extinguishing these formidable robbers of the artificial nourishment of the cultivated crops, than by bare fallowing, has yet been discovered. They are the rocks of the soil indeed, the practice of the best farmers of light land, however great their desire to extend the extent of bare fallow may be, is to have a portion of the land under fallow, though the extent of it may no doubt be limited by the want of manure, from a desire to keep their land clean and this is accomplished by summer following that portion of it which had carried potatoes in the preceding rotation, and leaving the potatoes and turnips on that part which had been previously thoroughly cleaned by summer following. This is a good practice, not only as a means of keeping land clean, but as following out that system of alternate husbandry of white and green crops, which has, by abolishing a succession of white crops with their scourging effect, tended more than any other to render the soil of these islands all alike fertile. But will summer fallow keep land clean? Undoubtedly it will, if properly performed. It gives the opportunity of working land in June and July when every crop should be in the ground, and when the sun is so powerful, and the atmosphere so warm and dry as to kill every plant that has not a hold of the ground. The process already described, of ploughing, harrowing and rolling, according to the state of the ground, is admirably adapted for cutting the matted land in pieces, for shaking the detached lumps of earth asunder, and for breaking in powder every hardened ball of earth into which the fibres or roots of weeds might penetrate, and the hand-picking cards off every bit of weed which might possess any latent vegetative power. Land that cannot be cleaned under such favourable circumstances as to season, must be seasonally sown, the season very wet and cold, or the following process conducted with great diligence. It must be understood, that following is too often worked very negligently. It is thought by some, that the land can be cleaned at any time before seed-time in autumn, and other things of less importance too often attend the situation from the more important fallow that weeds, though they do grow, can be easily ploughed down, and that the ploughing of them down assists to manure the land. Such thoughts too often prevail over better knowledge, and they furnish a strong argument in favour of increasing, rather than of diminishing, the means of cleanliness. But such thoughts display in their effects, great negligence and ignorance, in permitting any weeds to cover the land, particularly the root-growing ones, by which the strength of the soil is exhausted, and in losing the most favourable part of the season to accomplish their destruction and ignorance in thinking that weeds ploughed down afford nourishment to the soil, when that soil has been exhausting itself in bearing the crop of weeds. These are facts which are known to every practical farmer and the nature of which presses upon him a conviction of the necessity of summer fallowing more strongly than all the arguments that can be most speciously drawn, by analogy, from the practice of other arts. Reasoning from analogy is feeble when opposed to experience. Gardeners, indeed, raise crops every year from the same piece of ground, but their practice is not quite analogous to that of the husbandman. They apply a great quantity of manure to the soil, and they permit few or no plants to run to seed, the bringing of which to perfection, in the cereal crops, constitutes the great exhaustion to the soil. Gardeners, however do something like allowing their ground at stated periods, as every three or four years they dig the ground a double spit of the spade in depth, and lay it up in winter to the frost, and they reserve alternate pieces of ground for the support of late crops, all which practices approach hardly to our idea of summer fallowing." (*Clear Jour.* 4<sup>th</sup> vol p. 108.)

4940 *Fallow unnecessary on friable soils.* However necessary the periodical recurrence of fallow may be on retentive clays, its warmest advocates do not recommend it on turnip soils, or on any friable loams incumbent on a porous subsoil. Nor is it in any case necessary every third year according to the practice of some districts. On the best cultivated lands it seldom returns oftener than once in six or eight years, and in favourable situations an extra supply of manure, it may be advantageously dispensed with for a still longer period. (*Suppl. to Encyc. Brit. art. Agr.*)

4950 *The operation of following,* as commonly practised in England, is, in usefulness and effect, very different from what it ought to be. In most places the first furrow is not given till the spring, or even till the month of May or June or if it is given earlier, the second is not given till after midsummer, and on the third the wheat is sown. Land may rest under this system of management, but to clean it from weeds, to pulverise it, or to give it the benefits of aeration and heat, is impossible. The farmer in some cases purposely delays ploughing his fallows, for the sake of the scanty bite the couch and weeds afford to his sheep and for the same reason, having ploughed once, he delays the second ploughing. It is not to be wondered at, that under such a system, the theoretical agriculturist should have taken a rooted aversion from what are thus erroneously termed fallows. The practice of the best farmers of the northern counties is very different, and that practice we shall here detail.

4951 *A proper fallow invariably commences after harvest*, the land intended to be fallowed getting one ploughing, which ought to be as deep as the soil will admit, even though a little of the till or subsoil is brought up. This both tends to deepen the cultivated, or manured, soil as the fresh accession of hitherto unexploited earth becomes afterwards incorporated with the former manured soil, and greatly facilitates the movement of the roots of weeds during the ensuing fallow process, by cutting them completely from any connection with the fat subsoil. This autumnal ploughing usually called the winter furrow promotes the rotting of stubble and weeds; and, if not accomplished towards the end of harvest, must be given in the winter months, or as early in the spring as possible. In giving this first ploughing, the old ridges should be gathered up, if practicable, so as that they are kept dry during the winter months, but it is not necessary to split them out or divide them, especially if the land had been previously highly cultivated, so that each original ridge of land is divided into two half ridges. Sometimes, when the land is only laid dry, the furrows of the old ridges are made the creases of the new ones, or the land is ploughed in the way technically called *evening and furrow*. In other instances, two ridges are ploughed together, by what is called *marrow*, which has been already described. After the field is ploughed, all the inter furrows, and those of the headlands, are carefully closed up by the plough, and are afterwards gone over extremely by a harrow with spades, to remove all obstructions, and to open up the winter furrows into the finest ridges, whenever that seems necessary, that all moisture may have a ready exit. In every place where water is expected to lodge, such as ditches, or hollow places in the field, cross or oblique furrows are drawn by the plough, and their intersections carefully opened into each other by the spade. Whenever it appears necessary, cross cuts are also made through the head ridges into the ditches with a spade, and every possible attention is awarded, that no water may stagnate in any part of the field.

4952 *As soon as the spring seed-time is over* the fallow land is again ploughed and harrowed. If formerly split, it is now ridged up. If formerly laid up in gathered ridges, it is split or sown down. It is then

cross-ploughed; and after lying till sufficiently dry to admit the harrows, it is harrowed and rolled separately, and every particle of the vivacious seeds of weeds brought up to view, carefully gathered by hand into heaps, and either burnt on the field, or carried off to the compost heap. The fallow is then ridged up, which places it in a wet condition in the event of bad weather, and exposes a new surface to the harrows and roller. After which the weeds are again gathered by hand, but a previous harrowing is necessary. It is advantageously ploughed, harrowed, rolled, and gathered as often as it may be necessary to reduce it into the till, and completely to eradicate all root-weeds. Between these successive operations, repeated crops of seedling weeds are brought into vegetation and destroyed. The larvae hatching of various insects, together with an infinite variety of the seeds of weeds, are exposed to be devoured by birds, which are then the farmer's best friends, though often proscribed to his bitterest enemies.

4495. The use of the harrow and roller to the fallow process, has been condemned by some writers on husbandry, who allege that frequent ploughing is all that is necessary to destroy root-weeds, in the better or dryer of the soil in the sun and wind; but experience has ascertained, that frequently turning over the ground, though absolutely necessary while the fallow process is going on, can never eradicate root-grass or other root-weeds. In all they tell, the ground turns up in lumps or clods, which the several draughts will not penetrate so sufficiently as to kill the insulated tufts. When the land is again ploughed, these lumps are turned over and top more, and the bottom of the plough surface, in no degree to reduce them, or at least very imperfectly. It may be added, that these lumps preserve the entire formidable heads of weeds, which cannot be brought under the influence of the sun and air near the surface. The different use therefore, of the harrow and roller followed by gentle harrowing is absolutely necessary to the perfection of a fallow process. (*General Report of Scotland*, vol. iv. p. 419.)

4496. The method of falling by the grubber is an important modern improvement. We have already described several of these implements, and shall here introduce one which has been made public since the first five hundred pages of this work were printed.

4497. *Improved improved grubber* (fig. 751) has this peculiar structure, that the whole of the body of the harrow, and of course all the teeth can be raised out of the ground at pleasure, and even while the machine is in motion, which is extremely convenient, not only in turning in the land ridges,

but whenever an obstruction is met with in the ground, arising from rocky masses, or other insuperable soils. In such cases it would completely interrupt the progress of the ordinary instrument, this process with ease, by merely being lifted, and then being lowered again. This operation is performed by the driver having with his weight on the guiding handle of the grubber, and this pressure is made to raise the whole machine by a very slight application of mechanical power. The pressure on the guiding handle (a), it will be observed, turns the whole handle round the axis of the land wheels (b), as round a fulcrum, so that the handle then becomes a lever in the shortest extremity of which the frame of the tooth-draw, &c. is situated, thence, that by heaving on the handle which turns the long end of the lever the draw and teeth are raised, and along with it the hinder part of the tooth-draw, and, of course, the path steers. But there is still another contrivance, by which the frame is made to rest on the same time on the forepart of the frame, and to raise it likewise. This is done by a long rod (c), which is attached to the extremity of a fulcrum (d), raised on the handle frame, and at the other end of a short lever (e) which turns on the axis of the frame wheel (f), and at an intermediate point carries the fore end of the tooth-draw. While the handle, therefore, is depressed, and raises the hinder part of the tooth-draw at the same time pulls the rod, turns the short lever round the axis of the fore wheel, and by this means elevates the tooth below as well as below. The whole operation is simple, ingenious, and efficient. (*English Soc. Trans.* vol. viii. p. 153.)

751

4498. When effectively reduced to the till, and thoroughly cleaned from roots and weeds, the fallow is ploughed and long into gathered ridges or lands, usually fifteen or eighteen feet broad. If the seed is to be drilled, the lands or ridges are made of such widths as may suit the construction of the particular drill-machine to be employed. If the seed is to be sown by hand, the lands or ridges are commonly formed into what are called single or double past ridges: the first of four paces or steps, and the latter of eight steps in width. These widths are found the most convenient for a one-handed sower. An expert sower can, however measure his handful to almost any width, but the above long experience has made the standard. After the land has been once gathered by a deep furrow proportioned to the depth of the cultivated soil, the manure is laid on, and evenly spread over the surface, whether manure, lime, marl, or compost. A second gathering is now given by the plough, and this being generally the furrow upon which the seed is sown great care is used to plough as equally as possible. After the seed is sown and the land thoroughly harrowed, all the inter-furrows, furrows of the headlands, and oblique or gow furrows, are carefully opened up by the plough and cleared out by the spade, as already mentioned, respecting the first or winter ploughing.

4499. The expense of following may appear, from what has been said, to be very considerable, when land has been allowed to become stocked with weeds, but if it be kept under regular management, corn alternating with drilled pulses or green crops, the subsequent returns of fallow will not require near so much labour. In common cases, from four to six ploughings are generally given, with harrowing and rolling between, as may be found necessary, and, as we have already noticed, the cultivator may be employed to diminish this heavy expense. But it must be considered, that upon the manner in which the fallow operations are conducted, depend not only the ensuing wheat crop, but in a great measure all the crops of the rotation. (*Supp. to Encyc. Brit.* art. 449 128.)

### SECT. III. General Management of Manures.

4500. The manures of animal, vegetable or mineral origin have been already described, and their operation explained. (224.) But a very few of these substances can be obtained by farmers in general whose standard resources are farm-yard dung and lime, and composts of these with earth. It is on the management of these that we propose to deliver the practice of the best British farmers.

SUMMER. I. *Management of Farm-yard Dung.*

2453. The *beds of farm-yard dung* is straw, to which is added, in its progress through the farm-yard, the excrementitious substances of live stock. From every ton of dry straw, about three tons of farm-yard dung may be obtained, if the after-management be properly conducted; and, as the weight of straw per acre runs from one ton to one and a half, about four tons of dung, on an average of the different crops, may be produced from the straw of every acre under corn. (*Husbandry of Scotland*, vol. II.) Hence (it may be noticed) the great importance of cutting corn as low as possible; a few inches at the root of the stalk weighing more than double the same length at the ear.

2454. The conversion of *straw into farm-yard dung* in the stannery, is thus effected:—The straw is served out to cattle and horses in the houses and fold-yards, either as provender or litter; and commonly for both purposes; turnips in winter, and green clover in summer, are given to the stock both in the houses and yards. On this food the animals pass a great deal of urine, and afford the means of converting the straw into a richer manure than if it were eaten alone. All the dung from the houses, as they are cleaned out, is regularly spread over the yards in which young cattle are kept loose, where litter is usually allowed in great abundance; or over the dunghill itself, if there is one at hand. This renders the quality of the whole mass more uniform; and the horse-dung, which is of a hot nature, promotes the decomposition of the woody fibres of the straw.

2455. The preparation of the contents of the *farm-yard* for laying on the land, is by turning it over; or, what is preferable, serving it out to a dunghill. The operation of carting out is usually performed during the frosts of winter. It is then taken to the field to which it is to be employed, and neatly built in dunghills of a square form, three or four feet high, and of such a length and breadth as circumstances may require. What is laid up in this manner early in winter is commonly sufficiently prepared for turnips in June; but if not carried from the straw yards till spring, it is necessary to turn it once or oftener, for the purpose of accelerating the decomposition of the straw part of the mass. When dung is applied to fallows in July or August, nevertheless, to autumn sowing in winter, it is much less degree of putrefaction will suffice than for turnips. A dry soil, on which alone fallows should ever be resorted to, not requiring dung so much rotted as a finely pulverized turnip soil; and besides, as the wheat does not need all the benefit of the dung for some time, the woody fibre is gradually broken down in the course of the winter and the nourishment of the plants continued till spring, or later, when its effects are most beneficial.

2456. *Management of stable dung.* There is a most valuable paper on this subject by Lord Meadowbank, in the second volume of the *Transactions of the Board of Agriculture*. His lordship has ever found, that, instead of dung being the richest manure when completely fermented, it should, if possible, be laid on when very imperfectly fermented, but nevertheless when the process is going on at such a rate as that it must continue after mixture with the soil till it is completed. Every gardener knows, that the dung used in hot-beds has little effect in comparison of fresh dung; and every farmer knows, that a dunghill, which has by any accident been kept for years, is of little more value than so much very rich earth. Every person of attention, too, must have remarked the great effects which ensue from turning over a dunghill recently before using it, and that composts operate most powerfully, if used when sensibly hot, from the activity of the fermentation which the recent mixture of the ingredients has occasioned, and when, consequently that process is very far from being completed. As farm dunghills are formed by degrees, it is desirable to retard the fermentation of that which is first made, or to retain it in a state of fermentation, "so slow or imperfect, that it may suffer little till after being turned over with the later made dung, if there one powerfully fermenting mass; and that then it should be put into the soil, when the process is so far advanced that it will be completed, when, at the same time, little loss of substance has yet been suffered, and when what volatile matter is afterwards extricated will diffuse itself through the soil. In these circumstances, every thing is lodged in the soil that the dung can yield, either in point of mass or activity; and at the same time it is in a state when most likely to act as a powerful ferment, for promoting the putrefaction of the decayed vegetable lying inert in the soil. It certainly therefore, approves of the preservation of dunghills from much sun and much wind, as well as from that redundancy of moisture which is apt to overflow and wash away the manure; but I think the pressure which the feet of animals give them, especially of the lighter sort, does good, and prevents that violent fermentation which wastes the substance, and, in my opinion, exhausts the fertilizing powers of dung. This pressure contributes to preserve it fresh till the time of employing it as a manure calls for putting it altogether and at once, into that highly active state of putrefaction, which, though no doubt checked by its distribution in the soil, is sufficient to ensure a gradual and complete dissolution and diffusion of its substance. Unless, therefore, dung is to be used for composts, it appears to me clearly advantageous to get the dung into the soil as early as possible. It is always wanting somewhat, when kept out of it; but when put into the soil in a proper state, there is the utmost reason to think that what is extricated goes all to fertilize. Give me leave to add, that I do not believe much is lost by dissolution in rain water. I could never discover any thing of the kind in the water of the furrows of a field properly manured and ploughed. The case, every person knows, is quite different in fields recently limed or dressed with ashes; but I am apt to think that the volatile and soluble parts of common dunghills have some attraction with the substance of soils, that prevents their escape. We know that common leam extracts the noisome smell of the woollen cloths used for interposing the coarse silks that accompany spirits distilled from the sugar-cane, which secure any detestable bodies can obtain from it, and garden loam, impregnated as it must be with fermented dung, is certainly not easily deprived of its fertility by the washing of rain. I must also observe, that I take one of the great advantages derived from using dung with composts to be, the arresting and preserving the fertilizing matter which escapes in the putrefactive fermentation; and another to be, that dung there operates as a ferment, to putrefy substances not sufficiently disposed to putrefy with activity of themselves. You will observe, that this coincides exactly with the effects I have attributed to it upon soil, and affords a very useful parallel with respect to the substance to be used in lap-dresses, which are not to be covered with soil; viz. that if fermenting or putrefying substances are used, the process should have been completed, or nearly so, in a combination that has received the full benefit of it; that it is a great waste to spread common dung on grass, without having first mixed it with sand, leam, or other matter in which it has been dissolved and fixed; so that when spread on the ground, the leam, which would otherwise arise from fermentation and evaporation, is evoked; and that, if such a compost is used at the time when the plants are in a growing state, and in a way to cover it soon, it is by far the most advantageous method of laying it on. (*Crown R. Agr.* vol. II. p. 387.)

2457. The husbandman of *Brabant* is careful that his manure should never become parched and dried up, by which means all the volatile salts would evaporate. He lays his dung, as often as possible, close to his stables and cow-houses, and sheltered from the sun. If this cannot be avoided, he contrives to lay it under some large trees or perhaps of the shade of his hedges. As a recompense for their dung, they generally dig a pit five or six feet deep, with sufficient dimensions for the necessary deposit, from the month of March till harvest is over. The more opulent farmers are not satisfied with merely digging such a pit; they further pave and line it with bricks, that the earth should not absorb any of its parts; but that the thick matter should remain plunged in a mass of stale, increased further by rain. The stables and cow-houses are paved and sloped in such a manner as to communicate with a drain, which conveys all

the state of their cattle towards the dung pit, which, by this contrivance, it keeps constantly supplying." (*Chem. & Agr.* vol. II.)

4964. In the application of farm-yard dung to land under tillage, particular attention is paid to the cleanness of the soil and to use it at a time when, from the pulverisation of the ground, it may be most intimately mixed with it. The most common time of manuring with farm-yard dung is, therefore, either towards the conclusion of the fallowing operations, or immediately before the sowing of fallow crops. If no dung can be procured but what is made from the produce of the farm, it will seldom be possible to allow more than ten or twelve tons to every acre, when the land is managed under a regular course of white and green crops and it is thought more advantageous to repeat this dose at short intervals, than to give a larger quantity at once, and at a more distant period in proportion. (*General Report of Scotland*, vol. II. p. 517.) Farm-yard dung, it is well known, is greatly reduced in value by being exposed to the atmosphere in small heaps, previously to being spread, and still more after being spread. Its rich juices are exhale by the sun, or washed away by the rains, and the residuum is comparatively worthless. This is in an especial manner the case with long fresh dung, the far greater part of which consists of wet straw in an entire state. All careful farmers, accordingly, spread and cover in their dung with the plough, as soon as possible after it is brought on the land.

4965. The use of fresh dung is decidedly opposite to the practice of the best farmers of turnip soils; its inertness or rather injurious effects, from its opening the soil too much is a matter of experience with every one who cultivates drilled turnips on a large scale. As the whole farm-yard dung on such land, is applied to the turnip crop, it must necessarily happen that it should be laid on in different stages of putrefaction and what is made very late in spring often after a very slight fermentation or none at all. The experience of the effect of recent dung is accordingly very general, and the result, in almost every case, is, that the growth of the young plants is slow that they remain long in a feeble and doubtful state; and that they seldom, in ordinary seasons, become a full crop, even though twice the quantity that is given of short manure has been allowed. On the other hand, when the manure is considerably decomposed, the effects are immediate, the plants rise vigorously and soon put forth their rough leaf after which the beetle or fly does not seem on them and in a few weeks, the leaves become so large, that the plants probably draw the greatest part of their nourishment from the atmosphere. Though it were true, therefore, that more nutritive matter is given out by a certain quantity of dung, applied in a recent state, and allowed to decompose gradually in the soil, than if applied after undergoing fermentation and putrefaction, the objection arising from the slowness of its operation would in many instances, be an insuperable one with farmers. But there seems reason to doubt if fresh strawy manure would ferment much in the soil, after being spread out in so small a quantity as has been already mentioned and also if in the warm dry weather of summer the shallow covering of earth given by the plough would not permit the gaseous matters to escape to a much greater amount than if fermentation had been completed in a well-built covered dunghill.

4966. Another great objection to the use of fresh farm-yard dung is, that the seeds and roots of those plants with which it commonly abounds spring up luxuriantly on the land; and this evil nothing but a considerable degree of fermentation can obviate. The mass of materials consists of the straw of various crops, some of the grains of which, after all the care that can be taken will adhere to the straw of the dung of different animals yielded, as is often the case with horses fed on oats, with the grain in an entire state and of the roots, stems, and seeds of the weeds that had grown among the straw clover and hay and such as had been brought to the houses and fold-yards with the turnips and other roots given to live stock.

4967. The degree of decomposition to which farm-yard dung should arrive before it can be deemed a proper stable manure must depend on the texture of the soil, the nature of the plants, and the time of its application. In general, clayey soils, as more tenacious of moisture, and more benefited by being rendered imitative and porous may receive manure less decomposed than well pulverised turnip soils require. Some plants, too, seem to thrive better with fresh dung than others, potatoes in particular but all the small-seeded plants, such as turnips, clover carrots, &c. which are extremely tender in the early stage of their growth, require to be pushed forward into luxuriant vegetation with the least possible delay by means of short dung.

4968. The season when manure is applied, is also a material circumstance. In spring and summer, whether used for corn or green crops, the object is to produce an immediate effect, and it should therefore be more completely decomposed than may be necessary when laid on in autumn for a crop whose condition will be almost stationary for many months. (*Sup. Ency Brit.* art. *Agr.*)

4969. The quantity of putrescent manure requisite for each acre of land during each year is estimated, by Professor Coventry at five tons per acre annually. That quantity being supplied, not annually, but in quantities of twenty tons per acre every four years, or twenty-five tons per acre every five years. (*Quar Jour. Agr.* vol. II. p. 335.)

#### SUMMARY 2. Lime, and its Management as a Manure.

4970. Lime is by far the most important of the fossil manures; and, indeed, it may be asserted, that no soil will ever be fit for much which does not contain a proportion of this earth, either naturally or by artificial application. Next to farm-yard dung, lime is, in most general use as a manure, though it is one of a quite different character, and when judiciously applied, and the land laid to pasture, or cultivated for white and green crops alternately, with an adequate allowance of putrescent manure, its effects are much more lasting, and, in many instances, still more beneficial, than those of farm-yard dung. Fossil manures, Sir H. Davy observes, must produce their effect, either by becoming a constituent part of the plant, or by acting upon its more essential food, so as to render it more fitted for the purposes of vegetable life. It is, perhaps, in the spring of things

ways that wheat and some other plants are brought to perfection, after lime has been applied, upon land that would not bring them to maturity by the most liberal use of dung alone. This being an established fact may be considered one of the greatest importance to all cultivators.

4971. With regard to the quantity of lime that ought to be applied to different soils, it is much to be regretted that Sir Humphry Davy has not thought proper to enter fully into the subject. Clays, it is well known, require a larger quantity than sands or dry loams. It has been applied accordingly in almost every quantity from 100 to 500 bushels or upwards per acre. About 100 bushels are generally considered a full dressing for lighter soils, and 80 or 100 bushels more for heavy cohesive soils. One of the greatest advantages arising from the use of lime on gravelly or sandy soils, is its power of absorbing moisture from the air, which is in the highest degree useful to the crops in dry summers.

4972. In the application of lime to arable land, there are some general rules commonly attended to by diligent farmers, which we shall give nearly in the words of a recent publication

1. As the effects of lime greatly depend on its intimate admixture with the surface soil, it is essential to have it in a ready state at the time it is applied.
2. Lime having a tendency to sink in the soil, it should be ploughed in with a shallow furrow.
3. Lime may either be applied to grass land, or to land in preparation for green crops or summer fallow with almost equal advantage; but, in general, the latter mode of application is to be preferred.
4. Lime ought not to be applied a second time to heavy soils, unless mixed up as a compost, after which the land should be immediately laid down to grass.
5. Upon fresh land, the effect of lime is much superior to that of dung. The ground, likewise more especially where it is of a strong nature, is more easily wrought. In some instances, it is said, the saving of labour would be sufficient to induce a farmer to lime his land, were no greater benefit derived from the application than the opportunity thereby gained of working it in a more perfect manner. (*General Report of Scotland*, vol. II. p. 336.)

4973. In liming for improving hilly land, with a view to pasture, a much smaller quantity has been found to produce permanent and highly beneficial effects, when kept as much as possible near the surface, by being merely harrowed in with the seeds, after a fallow or green crop, instead of being buried by the plough.

4974. The successful practice of one of the most eminent farmers in Britain cannot be too generally known in a matter of so great importance to farmers of such land, especially when lime must be brought from a great distance, or was the case in the instance to which we are about to allude. "A few years after 1764," says Dawson, "having a considerable extent of outfield land in fallow which I wished to lime previously to its being laid down to pasture, and finding that I could not obtain a sufficient quantity of lime for the whole in proper time, I was induced, from observing the effects of fine loam upon the surface of similar soil, even when covered with heath, to try a small quantity of lime on the surface of this fallow instead of a larger quantity ploughed down in the usual manner. Accordingly, in the autumn, about twenty acres of it were well harrowed, and then about 600 six Winchester bushels only of unslacked lime were, after being slacked, carefully spread upon each English acre, and immediately well harrowed in. As many pieces of the lime, which had not been fully slacked at first, were gradually reduced to powder by the dew and moisture of the earth, to mix these with the soil, the land was again well harrowed in three or four days thereafter. This land was sown in the spring with oats, with white and red clover and ryegrass seeds, and well harrowed, without being ploughed again. The crop of oats was good, the plants of grass sufficiently numerous and healthy; and they formed a very fine pasture, which continued good until ploughed some years after for corn. About twelve years afterwards, I took a lease of the hilly farm of Grimbeth, many parts of which, though of an earthy mould tolerably deep, were too steep and elevated to be kept in tillage. As these lands had been much exhausted by cropping, and were full of couch grass, to destroy that and procure a cover of fine grass, I followed them, and laid on the same quantity of lime per acre, then harrowed, and sowed oats and grass seeds in the spring exactly as in the last-mentioned experiment. The oats were a full crop, and the plants of grass abundant. Several of these fields have been now above thirty years in pasture, and are still producing white clover and other fine grasses: no bent or ray has yet appeared upon them. It deserves particular notice, that more than treble the quantity of lime was laid upon fields adjoining, of a similar soil, but which being flatter for occasional tillage, upon which the lime was ploughed in. These fields were also sown with oats and grass seeds. The latter thrived well, and gave a fine pasture the first year; but afterwards the bent spread so fast, that, in three years, there was more of it than of the finer grasses."

4975. The conclusions which Dawson draws from his extensive practice in the use of lime and dung, deserve the attention of all cultivators of similar land

1. That animal dung dropped upon coarse heavy pastures, produces little or no improvement upon them; and that even when sheep or cattle are confined to a small space, as in the case of folding, their dung ceases to produce any beneficial effect, after a few years, whether the land is continued in pasture, or brought under the plough.
2. That even when land of this description is well fallowed and dunged, but not limed, though the dung augments the produce of the subsequent crop of grain, and of grass also for two or three years, that thereafter its effects are no longer discernible either upon the one or the other.
3. That when this land is limed, if the lime is kept upon the surface of the soil, or well mixed with it, and then laid down to pasture, the finer grasses continue in possession of the soil, even in elevated and exposed situations, for a great many years, to the exclusion of bent and moss. In the case of Grimbeth hills, it was observed, that more than thirty years have now elapsed. Besides this, the dung of the animals pastured upon such land adds every year to the luxuriance, improves the quality of the pasture, and augments the productive powers of the soil when afterwards ploughed for grain: thus producing, upon a heavy outfield soil, effects similar to what are experienced when rich inland lands have been long in pasture, and thereby more and more enriched.
4. That when a large quantity of lime is laid on such land, and ploughed down deep, the same effects will not be produced, whether in respect to the permanent firmness of the pasture, its gradual amelioration by the dung of the animals pastured on it, or its fertility when afterwards in tillage. On the contrary, unless the surface is fully mixed with lime, the coarse grasses will in a few years regain possession of the soil, and the dung thereafter deposited by cattle will not enrich the land for subsequent tillage.
5. Lastly, it appears from what has been stated that the four-shift husbandry is only proper for very rich land, or in situations where there is a full command of dung. That by far the greatest part of the land of this country requires to be continued in grass two, three, four, or more years, according to its

natural poverty; that the objection made to this, viz. that the coarse grasses in a few years weary exhaustion of the soil, must be owing to the surface soil not being sufficiently mixed with lime, the lime having been covered too deep by the plough. (*Farmer's Magazine*, vol. xiii. p. 68.)

#### SECT. IV Composts and other Manures.

4976. *Mixing farm-yard dung, in a state of fermentation, with earth*, in which there is much inert vegetable matter, — as the banks of old ditches, or what is collected from the sides of lanes, &c., — will bring this inert, dead matter, consisting of the roots of decayed grasses and other plants, into a state of putridity and solubility, and prepare it for nourishing the crops or plants it may be applied to, in the very manner it acts on peat. Dung, however mixed with earth, taken from rich arable fields which have been long cultivated and manured, can have no effect as manure to other land than the same earth and dung would not produce applied separately because there is generally no inert matter in this description of earth to be rendered soluble.

4977. *Mixing dung, earth, and quick-lime together* can never be advisable because quick-lime will render some of the most valuable parts of the dung insoluble. (See 2990.) It will depend on the nature of soil or earth, whether even quick lime only should be mixed with it to form compost. If there be much inert vegetable matter in the earth the quick-lime will prepare it for becoming food for the plants it may be applied to, but if rich earth be taken from arable fields, the bottoms of dung-pits, or, in fact, if any soil full of soluble matter be used, the quick-lime will decompose parts of this soluble matter combine with other parts, and render the whole mass less nourishing as manure to plants or crops than before the quick-lime was applied to it. Making composts, then, of rich soil of this description, with dung or lime mixed or separate, is evidently to say no more of it, a waste of time and labour. The mixture of earths of this description with dung produces no alteration in the component parts of the earth, where there is no inert vegetable substances to be acted on and the mixture of earth full of soluble matter with dung and quick-lime, in a mass together has the worst effects, the quick-lime decomposing and uniting with the soluble matter of the earth, as well as that of the dung thus rendering both in every case, less efficient as manures, than if applied separately from the quick-lime, and even the quick-lime itself inferior as manure for certain soils, than if it had never been mixed with the dung and earth at all. (*Farmer's Magazine*, vol. xv p. 351.)

4978. *Mixing dung in a state of fermentation with peat*, or forming what in Scotland are called Meadowbank middens (2941), is a successful mode of increasing the quantity of putrescent manure. The peat, being dug and partially dried, may either be carted into the farm-yard and spread over the cattle court, there to remain till the whole is carted out and laid upon a dunghill to ferment or it may be mixed up with the farm-yard dung as carted out. If care be taken to watch the fermenting process, as the fire of a clay-kiln is watched, a few loads of dung may be made to rot many loads of peat. Adding lime to such composts does not in the least promote fermentation, while it renders the most valuable parts of the mass insoluble. Adding sand ashes, or earth, will, by tending to consolidate the mass, considerably impede the progress of fermentation.

4979. *Bone manure*. Crushed bones were first introduced to Lincolnshire and Yorkshire, about 1800, by a bone merchant at Hull and the effect has been, according to a writer in the *British Farmer's Magazine*, vol. iii. p. 207, to raise wild unenclosed sheep-walks from 2s. 6d. or 5s. to 10s. 6d. or 30s. an acre. The quantity at present laid on is 12 bushels per acre drilled in, in the form of dust, with turnip seed. The turnips are fed off with sheep, and succeeded by a corn crop, and by two crops of grass. It seems to be generally admitted, that bone dust is not beneficial on wet retentive soils, as continued moisture prevents decomposition but in all descriptions of dry soils it never fails of success. On the poor soil, or chalk or lime-stone of the woods of Lincolnshire and Yorkshire, the turnip crops are said to equal those of any part of England and the barley, though coarse, to produce a greater quantity of saccharine matter than even the brightest Norfolk samples. (*Brit. Farm. Mag.* vol. iii. p. 208.)

4980. The *Dorchester Agricultural Association* appointed a committee, in 1856, to make enquiries, and report the results of them, on the use and advantages of bones as a manure. The report is full of interest, and highly satisfactory as to the great value of this species. The following is a summary of deductions from the details collected:—

1. That on dry sands, lime-stone, chalk, light loams, and peat, bones form a very highly valuable manure they may be laid on grass with great good effect and, on arable lands, they may be laid on fallow for turnips, or used for any of the subsequent crops.
2. That the best method of using them, when broad-cast, is previously to mix them up with earth, dung, or other manures, and let them lie to ferment.
3. That if used alone they may either be drilled with the seed or sown broad-cast.
4. That bones which have undergone the process of fermentation are decidedly superior to those which have not done so.
5. That the quantity should be about 25 bushels of dust, or 40 bushels of large, increasing the quantity if the land be impoverished.
6. That upon clays and heavy loams, it does not yet appear that bones will answer.

4981. Salt, nitre, and other substances have been already treated of in Part II. at sufficient length. It is clear that both salt and nitre may be advantageously used in many cases. Nitre continues to be a good manure used in Hertfordshire, on which it is sown at the rate of 1½ cwt. per acre. It has been tried at this rate in Scotland to wheat and to grass, and the effect is said to have been wonderful. Salt has been extensively used with almost every crop at different rates, from 20 to 40 bushels per acre, and it appears in many, if not in most, cases to have proved useful. (*Quar. Jour. Agr.* vol. i. p. 308., and *Highl. Soc. Trans.* vol. i. p. 147.)

## CHAP. II.

### Culture of the Cereal Grains.

4982. The corn crops cultivated in Britain are, wheat, rye, barley, and oats. Other culmiferous plants, as the maize, millet, and rice, have been tried with partial success in warm districts, but they have no chance of ever becoming general in our climate. The best description of the different species and varieties of Cerealia cultivated in Europe will be found in Metzger's *Europäische Cerealien in Botanischer und Landwirthschaftlicher Hinsicht*, &c. Heidelberg, 1824. Folio, 90 plates. The plates are exceedingly well executed and there are popular as well as scientific descriptions, with synonyms in all the European languages.

4983. On the culture of culmiferous plants, a few general remarks may be of use to the young farmer. Culmiferous plants, particularly wheat and rye, like most others, have two sets of roots. The first originate with the germination of the grain, are always under the soil, and are called the seminal roots; the second spring from the first joint which is formed near the surface of the soil, and from that joint strike down into the soil, these are called the coronal roots. The coronal roots appear chiefly intended for drawing nourishment from the soil, and, as Professor Martyn has observed, are judiciously placed for this purpose, the richest part of all soils being on or near the surface. These fibres are of larger diameter, more succulent, and never so long as the seminal. From these facts, as to the roots of culmiferous plants, some important hints may be derived regarding their culture. The use of stirring the surface in spring to facilitate the extension of the coronal roots, is obvious; the immediate effect of a top-dressing is also apparent, and also that manures may be ploughed in too deep to give the full amount of their beneficial effects to corn crops or grasses. Begeret, a scientific French agriculturist, proved experimentally, that where any of the grains or grasses are etiolated immediately after germination, by growing too rapidly or by being sown too thick or in too warm a season, the first joint from which the coronal or nourishing roots spring is raised above the ground, and in consequence either throws out no roots at all, or so few as to nourish it imperfectly, in which case it either dies before it comes into flower, or before the seed is matured. (*Mém. de la Soc. Ag. de Seine*, tom. ii.)

4984. Whether corn ought to be sown broadcast or in drills, is a question which has given rise to considerable discussion. The cultivation in rows of such plants as admit of intertillage during the summer months, is known to supersede the use of a summer fallow on lighter soils. "In truth, the row culture of certain green crops is one of the greatest improvements of modern agriculture, and should be established by every effort of instruction and example. By no other means yet known to us can so large a produce be raised from land under constant tillage, so beneficial a rotation of crops be adopted, or so great an economy be practised in the application of manures. But, while the advantages are thus apparent with regard to the application of this species of culture to our preparatory green crops, it does in no degree follow that advantages equally great will result from its application to our crops of white corn. The analogy, as it regards the nature of the plants which form the subject of cultivation, does not hold. The cereal grains send forth numerous shoots or suckers, and the goodness of the crop mainly depends on the vigour and number of the shoots which they send forth. The other kind of crops do not, generally speaking, tiller like wheat, barley, or oats, but rise from one stem. Reasoning from these principles, we should infer that the former class of plants should be cultivated in that manner in which they are best suited to summer tillage; that is, in rows: the latter in that manner in which the seed is most equally deposited in the upper stratum of the soil, which is in broadcast. The opinions, however, of intelligent agriculturists are not agreed as to the superiority in practice of the broadcast over the row system, even as it relates to the cereal grains. The farmers of Norfolk, or of the light soils of Sussex, will contend as strenuously for the superiority of the row system as the farmers of East Lothian for the broadcast system; and each may be right as it regards the application of the principle to the circumstances of his own situation. The question which is to be settled, however, is,—Which of the two systems

is to be regarded as the rule in husbandry, and which the exception? Now, — independently of the circumstances just adverted to, and judging only from the greater extent to which the broad-cast-system is carried on in the country from the fact of the row system having declined in favour in districts where it had once been most extensively practised; and from its having recently ceased to make progress in general practice, — we should be inclined to hold that, with respect to the cereal grains, the rule of agriculture is the broad-cast system, and the exception the row system. The cases falling under the exception may be, and doubtless are, very numerous and important. There are many light soils in which the seeds require to be deposited at a considerable and equal depth, and this the drill-machine effects better than sowing on the surface, and there are many thin cold clays which tend to throw out the plants, the best remedy for which is thought to be deep sowing."

485. The sowing of cereals from the hand, "however is known to be attended with some uncertainty; being dependent for the accuracy of the execution upon the skill and attention of the sower. The regularity of the work is also affected by winds; and unfortunately, the means rarely exist of detecting the degree of inaccuracy in the work until too late to correct it." As a remedy for these inconveniences, we have already described a broad-cast hand drill (3876.) and shall here introduce a horse machine for the same purpose (Fig 722 & 3.), that has been for some years employed in "the agriculture of Northumberland, North Durham, and some of the southern counties of Scotland, for sowing broad-cast. As it regards economy alone, little perhaps is effected by the employment of this machine. Its recommendations are the regularity and certainty with which it performs the work, and the rendering of the execution independent of unskilfulness or want of care in the operator" (*Quar Jour Agr* vol. II. p. 250.)

"A man and a horse with this machine will sow between 55 and 60 acres in a day. The regular manner in which the seed is disseminated renders less seed necessary than in the common method of sowing by the hand. Besides the advantages arising from a saving of seed, the greater regularity as it respects their distance from each other, with which the plants spring up, generally renders the crop superior to that sown in the other way. The machine has been described as adapted to the sowing of the common sorts of grain, but it is equally well calculated for sowing the cultivated grasses." (*Quar Jour Agr* vol. II. p. 254.)

486. The preservation of corn after it is threshed and cleaned is generally effected in granaries, where the grain is kept well ventilated by passing it frequently from one floor to another, or through winnowing machines.

487. It has been proposed and attempted in France to preserve it in pits or dry casks at an equal temperature, and insulated from the atmosphere, but the experiments now going on for this purpose, were

possibility by M. Chénier, at St. Omer, that Tribes, are not yet sufficiently matured to enable us to try any great amount of distillation. That such has been preserved in former ages, and that to a considerable extent, is beyond a doubt; and it is equally certain that in the interior of Africa, among the Caffres and other nations, as well as in the south of Russia, in Turkey, and in Egypt, the practice is still employed on a small scale. It may be doubted, we think, whether, with the present population of Europe, it could ever be generally adopted.

**4490. Preservation of corn in silos.** Some account of the opening of a silo was lately read in the Agricultural Society of Paris. "The place consisted of an innkeeper, and the grain when put in was of the finest appearance, perfectly dried, and in excellent condition. The door had been hermetically sealed; and, when opened, a considerable thickness of the mass of corn was found destroyed by weevils, the insects being in such quantity as to excite an elevated temperature. As part of the same corn had been previously and preserved in other silos, the cause of this deterioration was sought for, and a hole was found in the lower part which had been made by mice, and which, by admitting air in sufficient quantity, had allowed the weevils originally in the corn to live, and increase their numbers to the degree mentioned. After some observations upon experiments which showed that insects could live for a very long time in vitiated air, a committee was named to ascertain the requisite state of the air and the circumstances connected in the quantity with the preservation of grain in these repositories. At another meeting of the society, M. Bouché described the method proposed by M. Chénier to prevent the destruction of corn by weevils. It is founded upon a fact observed by him, that these insects cannot live in an atmosphere which contains less than a certain proportion of moisture. He therefore proposes that the corn should be subject to a continued ventilation of air dried by passing over quick-lime or chloride of calcium. All the weevils existing in the corn would thus be quickly destroyed." (*Recent Insects*, vol. xii, p. 308.)

**4491. The preservation of corn in the corn of Russia may deserve notice more as matter of curiosity and for suggesting ideas on the subject, than for instruction.** The corn is dried in small ovens or chambers, which communicate with a larger chamber or oven by small tubes that enter the smaller chambers at the top. The oven is then filled with straw closely pressed, which is lighted and left to consume during the night. Next morning the corn is taken from the smaller chambers, the smoke from the ovens having passed into them and perfectly dried it. This practice has several advantages: the corn is lighter to move and is kept much cooler without requiring to be constantly turned, being preserved from vermin by the smoke being communicated to it by the straw, which does not quit it until it has passed through the mill. The corn intended to be kept for any length of time is put into pits, in shape like a bottle, sufficiently high for a man to stand erect in, which are dug in elevated places with a sloping soil. When they are dug a fire is lighted for four and twenty hours, which forms a hard crust round the pit. The interior is lined with the bark of the birch tree, lashed with wooden nails. Some straw is then put at the bottom, upon which the corn is placed, and more straw at the top, the mouth of the pit being then closed with a wisp of straw in the form of a cone. Each pit contains from twenty-five to one hundred chetverts, and the grain in this will keep for twenty years without being injured. (*Méthode. Univer. de Genève*.)

**4490. The uses to which the straw of corn may be applied are various.** Besides food for cattle, litter for animals, thatch, &c., it is bleached and plaited into ribands for forming hats, and bleached, dyed of different colours, split, and glued to flat surfaces, so as to form various works useful and ornamental. Paper is also made from straw and the same pulp which forms the paper may be moulded into all the forms given to paper mache, medallion portraits, embossed works, &c. Whoever wishes to enter into the details of the great variety of articles that may be manufactured from straw, should consult the *Dictionnaire Technologique*, art: *Paille* or an abridged translation of a part of the article in Gill's *Technological Repertory*, vol. vi new series, p. 228.

**4491. The diseases peculiar to the cereal grasses have been included in the diseases common to vegetables in general (1671.)** They are chiefly the smut, the rust, the mildew and the ergot and we shall notice them more at length under the different species of corn which are most subject to suffer from them.

**4492. The practice of reaping corn before it is perfectly ripe originated in France, and has lately been recommended by M. Cadet de Vaux**

**4493. Corn reaped eight days before the usual time,** this author says, has the grain fuller, larger, finer and better calculated to resist the attacks of the weevil. An equal quantity of the corn thus reaped, with corn reaped at the period of maturity gave more bread, and of a better quality. The proper time for reaping is that when the grain, on being pressed between the fingers, has a doughy appearance like the crown of bread but not from the crumb, when pressed in the same manner. This does not seem to agree altogether with the experience of some agriculturists in the County of Gower, Pembrokeshire, where oats intended to be made into meal are always found to yield most when allowed to stand as long as possible. Corn for meal, however, it is acknowledged by the same agriculturists, will answer the purpose perfectly though cut before fully matured. (*Paris Miscellany*, vol. i, p. 61.) If the doctrine of Cadet de Vaux be confirmed or wholly true may be perhaps considered as confirmed by the following passage from Whistler:—"It is well known," he observes, "that wheat produces the most flour and the sweetest bread when threshed out before it has been stalked; and as all corn is more or less injured in both these respects, accordingly as it is more or less heated in the rack, it would be highly desirable totally to prevent its heating or becoming musty, in the racks. In wet harvests it is sometimes impossible to get corn sufficiently dried; and we see that even in hot and dry harvests, such as that of 1813, a great deal of corn is sometimes spoiled in the racks we should, therefore, be extremely curious to have corn well dried in the field, the racks made of a moderate size, and raised off the ground, to admit the air to circulate under them, with chimneys to allow a current of air to pass through them, to carry off the hot and musty air from the centre of the rack, which, without a chimney, has its tendency to heat four fold greater than one with a chimney. Chimneys being easily made, and so beneficial, it was to be wished that they were in general use." (*Mechanical Designer for 1815*, p. 101.)

**4494. The seed corn, it has only occurred that winter grain is** is, probably, but even that collected wheat and oats never perishes. Mr. A. Taylor, the miller of the *County Tower* and formerly an extensive farmer, has been in the practice of sowing from 100 to 120 acres of wheat annually for 30 years and upwards. "The seed was invariably chosen, not from the best and plumpest, but the thinnest and least misshapen seed." He has seen the most beautiful samples of wheat produced from seed of the most ordinary description. (*Quarterly Review*, March 22 1834.) In Pembrokeshire, the same is stated with respect to oats. (*Paris Miscellany*, vol. i, p. 61.)

**4495. The methods of reaping corn are various.** The most general mode is by the sickle, already described (2482. and 2483.); the scythe is also used, more especially for barley and oats; and a reaping machine (2737) is beginning to be used in some parts of Scotland; in which country an excellent bean-reaping machine (2740.) was

in use many years ago. A method of mowing corn much practised in the county of Durham, and possibly Yorkshire, has lately been introduced into Northumberland, but does not appear to make much progress, the low priced Irish reapers doing the work so much more neatly and with less waste, though it costs more money to the owner. The scythe has a cradle similar to that described (405.) It is handled and used differently from the bow and grass scythes, and has only one short handle or "rib" on the "sneel," or long handle, for the right hand; the left grasps the "sneel" with the palm upwards. This enables the mower, who generally mows "from the corn," to bring the back of the scythe and cradle to the ground, and leave the cut corn in a beautiful state for being put into sheaves. A good workman can do two, and some three acres a day: they charge about £s. per acre for mowing binding, and stooking (shocking) this practice may be advantageously followed wherever the crop is not stricken down by rains, particularly barley crops. (*C. near Dunelm, in Gord. Mag. vol. vi.*)

4996 *Frosted corn*, like frosted seeds of any sort, may be detected by dissection and comparison with unfrosted corn. By frosted corn is to be understood corn that has been frozen on the plant before it was perfectly ripe, in consequence of which the germ of the future plant or vital part of the seed is deprived of its vitality by the expansion produced by the freezing of its watery parts.

4997 *Frosted oats*. The oat being one of the latest crops, and a corn of cold rather than of warm countries, is more liable to be frozen than any other; but fortunately also, frozen oats are more easily detected than either frozen wheat or barley. The Rev James Farquharson who has paid much attention to this subject, and written an elaborate article on it in the *Farmer's Magazine* (vol. xix.) observes, that every kernel, when stripped of the husk, will be found to exhibit the appearance of a groove on one side. If the bottom of the groove has a smooth clear translucent appearance from end to end, if it is not much shrunk into the substance of the kernel, and if the kernel splits with difficulty in its direction, then we may pronounce the seed to be free from injury by frost. If, on the contrary, there is a black spot seen in the groove at the root end of the kernel, if the groove cuts deep into the kernel, so that it may be split in that direction, and if when the kernel is so split, the blackness, accompanied with a rotten rusty appearance, is seen extending from end to end at the bottom of the groove, then the vital part or future plant may be pronounced entirely unfit for being used as seed.

4998 *Frosted barley*. The nature of the injury that ripening barley suffers from frost is similar to that suffered by oats. The husk of barley like that of oats consists of two unequal parts, the small part covering the groove of the kernel. In sound grain when dry the hull is firmly attached to the kernel; but in frosted grain the small part of the hull becomes loose, and feels soft on being pressed, and if, in such grain this part of the hull is stripped away a blackness and rottenness, resembling that in frosted oats, will be seen in the bottom of the groove. In frosted barley the husk becomes loose all round the root end, but, as this is a circumstance that is occasionally observed likewise in barley that was never exposed to frost, it certainly sometimes arises from other causes, — perhaps from wet, and thus, unless the grain has germinated, does not render it unfit for seed or malting. The only sure mark of damage from frost is the blackness and rottenness in the bottom of the groove.

4999 *Frosted wheat*. Upon an attentive inspection of wheat that has been exposed to the frost, it will be observed that in a large proportion of grains there is a rotten acrid appearance where the embryo of the plant is attached to the cotyledon or meal part of the grain, that the groove is much deeper than in wheat that was sown before the frost, and that the grains are easily split in its direction. From this it is inferred that wheat, in its ripening stage, suffers from frost an injury of the same nature with that sustained by oats and barley. (*Farm. Mag. vol. xix.*)

5000 *The nutritive products of the plants to be treated of in this section, are thus given by Sir H. Davy*

Systematic Names.	English Names. The quantity analysed, of each sort 1000 parts.	Whole quantity of soluble or nutritive matter.	Starch or sugar.	Protein, or azote, or sugar.	Gluten or albumen.	Extract, or matter rendered insoluble during the operation.
<i>Triticum hybernum aestivum</i>	Middlesex wheat, average crop	955	765	—	190	—
	Spring wheat	940	700	—	240	—
	Mildewed wheat of 1806	210	178	—	38	—
	Blighted wheat of 1806	680	330	—	130	—
	Thick-skinned Sicilian wheat of 1810	925	735	—	230	—
	Thin-skinned Sicilian wheat of 1810	961	723	—	239	—
	Wheat from Poland	980	750	—	200	—
<i>Erdum vulgare avena sativa Secale cereale</i>	North American wheat	925	730	—	255	—
	Norman barley	920	750	70	80	—
	Oats from Scotland	745	644	15	87	—
	Rye from Yorkshire	789	545	58	109	—

SECT. I. *Wheat*. — *Triticum L. Triticaria Duggies L., and Gramineae J. Froment, Fr.; Weizen, Ger.; Grano, Ital.; and Tzgo, Span.*

5001 *Wheat is by far the most important of the cereal grasses, the flour made from its grains or seeds, from the quantity of gluten they contain, making the best bread in the world. A greater proportion of mankind are nourished by rice than by wheat, but there is no grain which comes near wheat in its qualities for bread-making. Rice and maize are comparatively unfit for it, and oats, barley, and rye but imperfectly adapted. Rye, however, comes nearer to wheat in its bread-making qualities than any other grain.*

5002 *Of what country wheat is a native, is totally unknown; it has been supposed indigenous to Asia and Africa, and unquestionably it is more likely to belong to those*

parts of the world than any other, but all that can be advanced on this subject is conjecture. Wheat, with the exception it is said of some parts of the southern coast of Africa, is cultivated in every part of the temperate and torrid zones, and in some places as high as 2000 feet above the level of the sea. It has been grown from time immemorial in India, but in few places at a greater elevation than 600 feet. Of course the elevation to which any plant can be cultivated always depends on the latitude of the situation.

\*8008. *Species and varieties.* (Fig. 722.) Botanists reckon seven species of *Triticum*, which are or may be cultivated for their grains, besides many varieties and subvarieties of these in common culture. The species or subspecies are,

- |   |  |
|---|--|
| 1. <i>Triticum polareum</i> , Summer wheat or spring wheat (s). | 2. <i>Triticum vulgare</i> , Field wheat (s).  |
| 3. <i>Triticum aestivum</i> , Common wheat (s).                 | 3. <i>Triticum aestivum</i> , Field wheat (s). |
| 4. <i>Triticum durum</i> , Hard wheat (s).                      | 4. <i>Triticum aestivum</i> , Field wheat (s). |
| 5. <i>Triticum spelta</i> , Spelt wheat (s).                    | 5. <i>Triticum aestivum</i> , Field wheat (s). |

The first, second, fourth, and fifth sorts are by many botanists considered as only varieties, and it is doubtful whether the third and sixth may not be the same, the seventh has all the marks of a distinct species, but it is very questionable whether, if much cultivated, it would always continue to produce one row of grains.

\*8009. *The spring or summer wheat (s),* *Blé de Mars*, Fr. is distinguished from that generally sown, by its narrower ears, longer heads, smaller grains, and shorter and more slender straw and also by its liability to endure our winters. It is commonly sown in April, or even so late as May. It was known to Parkinson in 1635, but has never been much cultivated except in Lincolnshire. It was tried and given up in Northumberland and Mid Lothian, and also in some counties near London. Many varieties of summer wheat were transmitted a few years ago to the president of the Board of Agriculture from the Agricultural Society of Paris, for the purpose of experiment, and were divided among several distinguished agriculturists, (*Observe to the Board of Agr.*, vol. vi. p. 11); but there has not yet been time for establishing their comparative merits, or their adaptation to the climate of Britain. Summer, or as it is often called, spring, wheat has however been long and extensively cultivated in some parts of England, particularly in Lincolnshire; and it is probable may be found a valuable crop in the southern counties; but the trials that have been made in the north, do not seem to entitle it to a preference over winter wheat sown in spring, or even oats or barley in that climate.

\*8010. *Of the winter or common wheat (s),* *Froment blanc*, Fr., there are a great number of varieties. Professor Martyn, in Miller's Dictionary, has described forty-nine sorts, and Professor Theser speaks of a hundred, but avows that those who describe them know nothing about them, and in all probability include one sort under different names. All the varieties may be reduced to two, the white, and the brown or red grained. As subvarieties, there are the bearded and beardless, the woolly-chaffed, and thin or hairy chaffed, both of the red and white. To these come still another variety, which is the spring-sown common wheat. It is stated by those who maintain that this variety exists, that through long sowing the progeny after a number of generations, acquires a habit of coming earlier into blossom than seed from winter-sown grain. This we think very likely, but are not aware that the variety is distinctly known by any remarkable marks in the plants. The red or brown wheats are universally considered more hardy than the white, but as yielding an inferior flour, the woolly white is supposed to yield the best flour; but woolly-chaffed wheats are considered more liable to the rust than any other.

\*8011. *The Egyptian, or many-grained wheat (s),* *Blé de Séville ou de Smyrne*, Fr. the turgid grey pointed or duck-like wheat (s), and the Field wheat (s), may for all agricultural purposes, be considered only varieties of the common winter wheat. They are cultivated in a few places in England, and seeds of them may be procured from the public botanic gardens, but they are in little estimation.

\*8012. *Hard wheat (s),* the *Species of the French*, is known by its short straw, which is almost solid, and by its strong glume, with other peculiarly curved, the ears long and stiff. The chaff adheres so closely to the grain as not to be separated without great difficulty. This grain, as we have seen, is a good deal sown in the north of Europe. In France it is sown in spring, on land too coarse for common wheat, and it ripens in July and August. It is the principal wheat sown in Russia and the north of Switzerland; and is a good deal sown in Spain. The grain is light, and yields but little flour; but it is said to contain a larger portion of gluten than common wheat, and for that reason is recommended as superior to any other in bakery and confectionary. It is not cultivated in Britain.

\*8013. *The one-grained wheat (s),* *Field spelt wheat*, Fr., is known by its small thin spike, and single row of grains; the leaves and straw are remarkably small, yet very hard; and the plants tiller very much. It is chiefly cultivated in the mountainous parts of Switzerland, where its straw, like that of the former species, is much used for sheathing. The grain makes a brown light bread; but its great excellence, according to Villars, is for grass.

8009. To procure new varieties of wheat the ordinary mode is to select from a field a spike or spikes from the same stalk, which has the qualities sought for; such as larger grains, thinner chaff, stiffer straw, a tendency to earliness or lateness, &c.; and picking out the best grains from this ear or ears, to sow them in suitable soil in an open dry part of a garden. When the produce is ripe, select the best ears, and from these the best grains, and sow these, and so on till a bushel or more is obtained, which may then be sown in a field apart from any other wheat. In this way, many of the varieties of our common winter wheat have been obtained, as the hedge-wheat which was reared from the produce of a stalk found growing in a hedge in Sussex, by one Wood, about 1780. Other varieties have assumed their distinctive marks from having been long cultivated on the same soil and climate, and take local names, as the Hertfordshire red, Essex white, &c.

8010. Marshall, (Yorkshire) mentions a case in which a man of accurate observation, having in a place of wheat a plant of uncommon strength and luxuriance, diffused its branches on every side, and setting its closely-surrounding neighbours at defiance, marked it; and at harvest removed it separately. The produce was 15 ears, yielding 604 grains of a strong-bodied liver-colored wheat, differing in general appearance, from every other variety he had seen. The chaff was smooth, without awns, and of the colour of the grain; the straws stout and ready. These 604 grains were planted singly nine inches asunder, filling about 40 square yards of ground, on a clover stubble, the remainder of the ground being sown with wheat in the ordinary way; by which means extraordinary trouble and destruction by birds were avoided. The produce was two gallons and a half weighing 90 lbs. of prime grain for seed, besides some pounds for seconds. One grain produced 35 ears, yielding 1335 grains; so that the second year's produce was sufficient to plant an acre of ground. What deters farmers from improvements of this nature is probably the mischievousness of birds from which at harvest it is scarcely possible to preserve a small patch of corn, especially in a garden or other ground situated near a habitation; but by carrying on the improvement in a field of corn of the same nature, that inconvenience is got rid of. In this situation, however the botanist will be apprehensive of danger from the feral farms of the surrounding crop. But from what observations Marshall has made he is of opinion his fears will be groundless. No evil of this kind occurred though the cultivation of the above variety was carried on among white wheat.

8011. But the most systematic mode of procuring new varieties, is by crossing two sorts, as to breeding; that is, by impregnating the female organs of the blossom of one ear with the strobilating matter or pollen of the male organs of the blossom of another variety of a different quality. Thus, supposing a farmer was in the habit of cultivating a very good variety which he wished to render somewhat earlier let him procure in the blossoming season, from a very early soil, some spikes of an early sort just coming into blossom; and let him put the ends of these in water and set them in the shade so as to retard their fully blossoming till the plants he has destined to become the females come into flower. Then let him cut out all the male organs of the latter before they have advanced so far as to impregnate the stigma, and, having done this, let him dust the stigma with the blossoming ears of the early or male parent. The impregnated stalks must then be kept apart from other wheats that the progeny may be true. When the grains ripen, let him sow the best, and from the produce when ripe select the earliest and finest spikes for seed. Let him now these and repeat the choice till he procures a bushel or two of seed. This operation has been successfully performed by T. A. Knight (1833); and though it may be reckoned too delicate for farmers in general, it will be looked on by the philosophical agriculturist as not improbably leading to results as important as those which have attended the practice in the case of garden fruits and flowers. The scientific farmer may consult on this subject Bishop's *General Botany* already referred to, the *Gardener's Magazine*, and *Saggio Botanico Geografico intorno l'istituzione delle Pianta*, by Billardi. Paris, 1820.

8012. The propagation of wheat by transplanting may be employed to expedite the progress of cultivating a new variety of ascertained excellence. To show what may be gained in time by this mode, we shall quote from *The Philosophical Transactions* an account of an experiment made by C. Miller, son of the celebrated gardener of that name, in 1768. On the 2d of June Miller sowed some grains of the common red wheat; and on the 8th of August, a single plant was taken up and separated into 18 parts, and each part planted separately. These plants having pushed out several side shoots, by about the middle of September some of them were then taken up and divided, and the rest of them between that time and the middle of October. This second division produced 67 plants. The 6 plants remained through the winter and another division of them, made about the middle of March and the 12th of April, produced 500 plants. They were then divided no further but permitted to remain. The plants were in general, stronger than any of the wheat in the fields. Some of them produced upwards of 100 ears from a single root. Many of the ears measured seven inches in length, and contained between 60 and 70 grains. The whole number of ears which by the process above mentioned, were produced from one grain of wheat, was 21,108, which yielded three pecks and three quarters of clean corn, the weight of which was 67 lbs. 7 ounces and, from a calculation made by counting the number of grains in an ounce, the whole number of grains was 336,848. By this account we find, that there was only one general division of the plants made in the spring. Had a second been made, MILLER thinks the number of plants would have amounted to 9000 instead of 500, and the produce thereby much enlarged.

8013. In making a choice from all the species and varieties which we have named, the thin-skinned white wheats are preferred by all the best British farmers whose soil and climate are suitable for this grain, and for sowing in autumn. In late situations, and less favourable soils and climates, the red varieties are generally made choice of and these are also generally preferred for sowing in spring. Red wheats, however, are considered as at least fifteen per cent. less valuable than the white varieties. No subvariety ever continues very long in vogue, nor is it fitting that it should, as degeneracy soon takes place, and another and better is sought for as a successor. Hence the only recommendation we can give, as to the choice of subvariety, is, to select the best from among those in use by the best farmers in the given situation, or nearest well-cultivated district.

8014. The soils best adapted for the culture of wheat, are rich clays and heavy loams; but these are not by any means the only description of soils on which it is cultivated. Before the introduction of turnips and clover, all soils but little calcareous were thought unfit for wheat; but, even on sandy soils, it is now grown extensively, and with much advantage, after either of these crops. The greater part of the wheat crop throughout

Wheat, however, is probably still sown upon fallowed land. When it succeeds turnips cut on the ground, or clover cut for hay or soiling, it is commonly sown after one ploughing. In Scotland, when wheat is to be sown after clover upon heavier soils, or after grass of two or more years, the land is ploughed twice or thrice, or receives what is called a rag fallow. In Norfolk and Suffolk, wheat is seldom sown after fallow or turnips; but the farmer there thinks himself almost sure of a good wheat crop after a good clover crop. One ploughing only is required, and the seed is dibbled in the flag, as they call it; that is, on the turned-over surface or furrow slice.

2015. On rich soils, wheat may be cultivated almost every second year, provided due care is taken to keep the land clean, and in good condition. A summer fallow once in four, six, or eight years, according to climate and circumstances, is, however, necessary, and manure should either be applied on that fallow for the first crop of wheat, or, what some people think preferable, should be laid on the wheat-stubble for a crop of drilled beans, which ensures the succeeding crop of wheat. If the first crop of beans has been consistently cleared, there is no difficulty in repeating, and even in extending the course; and the crops will be little inferior to those gained at the beginning of the rotation, provided manure has been bestowed to each crop of beans. In this way when the ground is fallowed every fourth year, two crops of wheat and one of beans are gained from manuring once; when fallowed every sixth year, three crops of wheat and two of beans are gained from manuring twice; and, when fallowed every eighth year, four crops of wheat and three of beans from manuring thrice. In the first-mentioned shift, less manure is bestowed than in either of the other two, if the soil is of good quality it will support itself; whereas, in the shift of six and eight, unless foreign manure be procured, it rarely happens that they can go on successfully for any length of time, without abstracting dung from other parts of the farm on which they are practised. (*Brown's Tr. on Rural Affairs.*)

2016. In cultivating wheat on this class, the rotations just mentioned are inapplicable. A six-course shift of a different kind has, however, been successfully followed by many people; but it requires every branch of the work to be well executed. Ist, a summer fallow dunged at the rate of twelve or fourteen double loads per acre; 2d, wheat; 3d, grass; 4th, oats; 5th, peas and beans drilled; 6th, wheat. If manure can be given in the middle of the shift, every one of the crops may be expected good; but if that is withheld, there will necessarily be a proportionable falling off in the two last crops. Husbandmen must, however, regulate their practice according to their means, though it deserves to be remarked, that, if greater attention were paid to the collection of materials which ultimately are converted into manure, many deficiencies in the article would be fully supplied. (*Brown.*)

2017. Excellent wheat may be grown on light soils, with the exception of soft sands. Such soils, however, are not constitutionally disposed to the growth of that grain, nor will they, under any management, bear such a frequent repetition of it as those already mentioned. Summer fallow on them may safely be dispensed with; because a crop of turnips, which admits every branch of the cleaning process to be more perfectly executed than even a naked or bare fallow does, may be profitably substituted. Wheat here comes in with propriety after turnips, though, in general cases, it must be sown in the spring months, unless the turnips are stored; in which case it may be sown in November or it may be sown after clover, for the fourth crop of the rotation, or in the sixth year, as a way-going crop, after drilled peas and beans, if the rotation is extended to that length. But, take it any way, it is scarcely possible to raise wheat as extensively upon light soils, even where they are of the closest quality as is possible upon clay, nor will a crop of equal bulk upon the one, return so much produce in grain as may be got from the other. To enlarge upon this point would only serve to prove what few husbandmen will dispute, though it may be said, that, on thin sands, wheat ought not to be ventured, unless they are either completely clayed or marled, as it is only with the help of these auxiliaries that such a soil can gain stamina capable of producing wheat with any degree of success. (*Brown.*)

2018. The culture of the soil intended for wheat varies according to its nature, and the preceding and following crops.

2019. The soils really calculated for wheat, though in different degrees, summer fallow is the first and besting day to give a good crop or crops of that grain. The first furrow should be given before winter or so early as other operations upon the farm will admit; and every attention should be used to go in as deep as possible; for it rarely happens that any of the succeeding furrows exceed the first one in that respect. The number of after-ploughings must be regulated by the condition of the ground and the state of the weather; but, in general, it may be observed, that ploughing in length and across, alternately is the way by which the ground will be most completely cut, and the intention of fallowing accomplished. It has been argued, that harrowing clay soils, when summer fallowed, is prejudicial to the wheat crop; but without discussing this point (such a discussion being unnecessary), it may merely be stated, that, in a dry season, it is almost impracticable to reduce real clays, or to work them too small; and that, even in a wet one, supposing they are made surface-smooth they will, when ploughed up again, consolidate into clods or big lumps after forty-eight hours' drought, and become nearly as obdurate as ever. It is only on thin soils, which have a mixture of peat earth, and are incumbent on a bottom impervious to water, that damage is at any time sustained by over-harrowing. Such are generally of a weak texture, and may be broken down with facility by the roller and harrow. If caught by rough rain before the pores are in some measure closed, the moisture is greedily absorbed; and being prevented from going downwards by the hardness of the subsoil, the whole surface becomes a kind of mortar or paste, unless previously well ridged up; which, to a certain extent, prevents the consequences from being dangerous. These evils, however, must be submitted to by the possessor of such soils, if they want to have them sufficiently fallowed and prepared for a proper sowing; for, without reducing them, couch-grass, and especially moss, with which they are commonly stored, cannot be eradicated. If they are reduced in the early part of the season, the danger is small; but to break them down in the later part ought always to be avoided, unless called for by important necessity.

2020. When wheat is sown after beans it usually happens, in this northern climate, that more than one ploughing may be successfully bestowed. Indeed, if this is given, it is advantageous to cross-harrow the land, which levels the drills, and permits the ploughing process to be executed with precision. Almost in every case the ridges should be gathered up, so that the furrows may be well cleared out, and the plants preserved from injury during the inclement winter season. Clover land should be neatly ploughed, and well laid over, so that the roots of the grasses may be buried and destroyed; for it frequently happens that crops of wheat, after clover and ryegrass, are greatly injured by incision to the ploughing process. In short, sowing wheat after clover on clay soils in Scotland may be considered as the most hazardous way in which that grain can be cultivated. (*Brown's Tr. on Rural Affairs.*)

2021. The manures best calculated for wheat, are allowed by all agricultural chemists to be animal matters and lime. The former has a direct influence in supplying that essential constituent to wheaten flour, gluten; and the latter acts and lime, both actually found in the straw of wheat. At all events, it is certain that wheat will not

thrive on any soil which does not contain lime. In this Sir H. Davy, Chaplin, Professor Thaez, and Griesbach fully agree.

5022. *A more abundant supply of manure is generally required for wheat than for any other grain.* Professor Thaez says it absorbs more nourishment from the soil than any of the cereals; and its calcareous (hypothetically as he allows) that for every 100 parts of nutriment in a soil sown with this grain, 40 will be carried off by the crop. (*Practical Husbandry, &c.* p. 202.) At the same time, he says a dose of manure on land in good till is very apt to cause the crop to rot; and hence some people think it improper to dung rich clays or loams when fallowed, and choose rather to reserve that treatment till the succeeding season, when they are prepared for a crop of delicate herbage. Delaying the manuring process for a year is attended with many advantages, because good land, fully manured, requires a principle of action within itself, at often causes the first wheat crop to be injured before it is filled under which circumstance, the produce is diminished both in quantity and quality. The delay in manuring is, however, attended with disadvantages; because, when dung is kept back till the end of autumn or beginning of winter to be laid on the stubbles, the weather is often so wet that it cannot be carted so without subjecting the land to injury from poaching, whilst the labour in laying it on is also increased. On thin clays, or even upon soils of the other description not in high condition, there can be no doubt but that the end of summer and upon summer fallow is the most proper time for manuring, though it will be found, that an imprudent expenditure of dung on such occasions ought always to be steadily avoided. (*Brown.*)

5023. *Where manure is abundant,* it is stated by some that wheat alternating with a green crop, or indeed any corn crop and a green crop, may be grown alternately for an indefinite time. (*Rural Mag.* vol. xxii. p. 382.) It is alleged by others, that this doctrine is not supported by experience. Commonly, they say, where out the best soils and the grain degenerates in quality if not in quantity too. Instances, however, are given in *The Communications to the Board of Agriculture* of potatoes and wheat having been grown alternately on the same soil for a number of years, and very good crops produced. It may be useful to know that the thing is not impossible.

\*5024. *The climate required to bring wheat to perfection must be such as affords a dry and warm season for the blossoming of the ear and the ripening of the grain.* Wheat will endure a great deal of cold during winter if sown in a dry or well drained soil and if it be covered with snow. Hence it is that wheat is sown as far north as Petersburg and in Sweden. Moderately moist weather before the flowering season, and after the grain is set or formed, is favourable to wheat but continued heavy rains after the flowering season produce the smut. The dry frosty winds of February and March and even of April in some districts, are more injurious to the wheats of Britain than any other description of weather. Hoar frosts, when the plant is in the ear produce blights and mildews often result from or follow sultry winds and fogs. Cold, in the blossoming and ripening season in July, even unaccompanied by wind or rain, produces an inferior grain, greatly deficient in gluten and next the contrary. The most valuable wheat of Europe, in this respect, is that of Sicily which Sir H. Davy found to contain much more gluten than the best wheat of Britain.

5025. *The season for sowing wheat on clays is generally the latter end of autumn on early turnip soils it is sown after clover or turnips, at almost every period from the beginning of September till the middle of March but the far greater part is sown in September and October.* For summer wheat, in the southern districts, May is sufficiently early but in the north, the last fortnight of April is thought a more eligible seed-time. In the cultivation of spring-sown winter wheat, it is of importance to use the produce of spring sown grain as seed, as the crop of such grain ripens about a fortnight earlier than when the produce of the same wheat winter-sown is employed as spring seed. (*Encyc. Brit. art. Agr.*)

5026. *Seed wheat is prepared for sowing by the process called pickling.* According to Brown (*Treatise on Rural Affairs, art. Wheat*) this process is indispensably necessary on every soil otherwise smut, to a greater or less extent, will, in nine cases out of ten, assuredly follow.

5027. *Though almost all practical farmers are agreed as to the necessity of pickling yet they are not so unanimous as to the mode of performing the process, and the article which is best calculated to answer the intended purpose.* Stale urine may be considered the safest and surest pickle, and where it can be obtained in a sufficient quantity it is commonly resorted to. The mode of using it does not, however seem to be agreed upon; for, while one party contends that the grain ought to be steeped in the urine, another party considers it sufficient to sprinkle the urine upon it. Some, again, are advocates for thoroughly steeping the grain in a pickle made of salt and water, sufficiently strong to buoy up a fresh egg. But whatever difference of opinion there may be as to the kind of pickle that ought to be used, and the mode of using it, all admit the utility of mixing the wetted seed with hot lime, fresh slaked; and this, in one point of view is absolutely necessary, so that the seed may be equally distributed. It may also be remarked, that this last mode is often justified the utility of all these modes, provided they are attentively carried into execution. There is some danger from the first; for if the seed steeped in urine is not immediately sown, it will infallibly lose its vegetative power. The second, viz. sprinkling the urine on the seed, seems to be the safest, if performed by an attentive hand; whilst the last may do equally well if such a quantity of salt be incorporated with the water as to render it of sufficient strength. It may also be remarked, that this last mode is often unaccompanied with merit, giving no doubt to a deficiency of strength in the pickle; whereas a single bushel with smut is rarely discovered when urine has been used.

5028. *An improved mode of preparing wheat for sowing has recently been adopted in the south of Scotland, and followed with great success.* It is thus described:—“Take four vessels, two of them smaller than the other two, the former with wire bottoms, and of a size to contain about a bushel of wheat, the latter large enough to hold the smaller within them. Fill one of the large tubs with water, and putting the wheat in the small tub, immerse it in the water, and stir and stir off the grains that float above, and renew the water as often as is necessary till it comes off almost quite clean. Then raise the small vessel in which the wheat is contained, and repeat the process with it in the other large tub, which is to be filled with stale urine; and in the mean time wash more wheat in the water tub. When abundance of water is at hand, this operation is by no means tedious; and the wheat is much more effectually cleansed from all impurities, and freed more completely from weak and unhealthy grained seeds of weeds, than can be

death by the sowing machine. When thoroughly washed and skinned, let it drain a little, then empty it on a clean floor or in the cart that it is taken to the field, and stir quicklime upon it, turning it over and stirring it with a shovel till it is sufficiently dry for sowing." (*Supp. R. Agr. Soc. Agr.*)

9029. The quantity of seed necessarily depends both on the time of sowing and the state of the land; land sown early requiring less than the same land when sown in winter or spring; best sown land being at all times allowed more seed than rich. The quantity necessarily varies from two bushels, or less, to three, and sometimes even to four bushels per English statute acre. Winter wheat, when sown in spring, ought always to have a liberal allowance, as the plants have not time to tiller much without unduly retarding their maturation. (*Supp. Agr.*) Upon well prepared lands, if the seed is distributed equally, it can scarcely be sown too thin, perhaps two bushels per acre not sufficient; for the heaviest crops at autumn are rarely those which show the most vigorous appearance through the winter months. Bean stubbles require more seed than summer fallows; because the roughness of their surface prevents such an equal distribution; and clover layers ought to be still thicker sown than bean stubbles. Thin sowing in spring ought not to be practised, otherwise the crop will be late, and imperfectly ripened. (*Brown.*)

9030. The modes of sowing wheat are either broad-cast, drilling, ribbing, or dibbling. The first mode is by far the most general, more especially in the north of England and Scotland, and the seed is for the most part covered by the harrows. No more harrowing, Brown observes, should be given to fields that have been fallowed than what is necessary to cover the seed, and level the surface sufficiently. Ground which is to lie in a broken-down state through the winter, suffers severely when an excessive harrowing is given, especially if it is incumbent on a close bottom, though as to the quantity necessary none can give an opinion except those who are present.

9031. *Floughing in.* Many farmers allege that wheat which is harrowed in is apt to be thrown out in spring, or if not thrown out at that season, that it does not tiller well, and that the stalks are apt to divide away and fall down in the flowering season. It is certain that this is the case in many parts of England; and the cause assigned by the northern farmers is the defective manner in which the land is ploughed, by which there is not sufficient covering for the seed. To guard against these evils it is a very general practice in most of the southern counties, when wheat is sown broad-cast, to plough it in with a shallow harrow. This is done even after beans and on clover leys, and is a favorite practice on very opposite soils, as in Norfolk and Middlesex.

9032. *Drilling*, however, is extensively practised in some districts, and is becoming more general on lands indented with the seeds of annual weeds, especially when sown in spring. A machine which sows at three different intervals, according to the judgment of the farmer of twelve, ten and a half, or nine inches, is much approved of in the northern districts. It deposits six, seven, or eight rows at once, according to its adjustment to one or other of these intervals, and the work is done with ease and accuracy when the ridges are previously laid out of such a breadth (twelve feet and a half) as to be sown by one beast; the machine going along one side of such a ridge, and returning on the other, and its direction being guided by one of its wheels, which does always run in the open furrow between the ridges. If the ten and a half inch interval be adopted, and it is the most common one in that country the machine sows seven rows at once, or fourteen rows on a ridge of twelve feet and a half. But the space between the rows varies in some parts still more than this machine admits of, it might not, however, be so narrow as to prevent hand-weeding, even after the crop has made considerable progress in growth and it cannot advantageously be so wide as to admit the use of any effective horse-hoe.

9033. *Dibbling* is a mode of sowing common in some places, by which a drill machine is dispensed with, though the same purpose is nearly answered. Thus we have already adverted to in the section on tillage. The seed is scattered with the hand in the usual broad-cast manner, but as it necessarily falls for the most part in the furrows between the ribs, the crop rises in straight parallel rows, as if it had been sown by a drill machine. After sowing, the ribs are levelled by harrowing across them. This plan has nearly all the advantages of drilling in, as far as it regards exposure to the rays of the sun, and the circulation of air among the plants; but as some plants must always rise between the rows, it is not quite so proper when hoeing is required. (*Supp. R. Agr.*)

9034. The *dibbling* of wheat is practised in some parts of Norfolk. The furrow is laid over flat, and a row of holes is made along the middle of each by a man who uses a dibber in each hand. A middling workman will make four holes in a second. One dibber is sufficient for three droppers; whence one man and three children are called a set. The dibbler carries on three flags or turned furrows, going on some yards upon one of the outside furrows, and returning upon the other after which he takes the middle one; and thus keeps his three droppers constantly employed; and at the same time is in no danger of filling up the holes with his feet. The droppers put two or three grains of wheat into each hole but much time and patience is necessary to teach them to perform the business properly and quickly. An expert dibbler will make half an acre in a day; though one third of an acre is usually reckoned a good day's work. The seed is covered by means of a bush harrow and from one bushel to six pecks is the usual quantity for an acre. Notwithstanding the advantages of sowing seed, as well as some others which are generally reckoned undeniable, it is asserted by some very judicious farmers, that dibbling of wheat on the whole is not really a profitable practice. It is particularly said to be productive of weeds, unless dibbled very thick which, indeed, very probably be the case, as the weeds are thus allowed a greater space to vegetate in. Marshall is of opinion, that the dibbling of wheat appears to be peculiarly adapted to damp rich soils, on which three or four pecks dibbled early may spread sufficiently for a full crop; whence light, well-shallowed soils, which have less than two or three years, and have become greasy require an additional quantity of seed, and consequently an addition of labour, otherwise the plants are not able to reach each other, and the grasses of course find their way up between them, by which means the crop is injured, and the soil rendered foul. It is alleged, that if a single grain of good size and sound could be dropped in each hole and no more, there might be an advantage in dibbling, above it would be accomplished at a moderate rate; but where two or three grains are put in each hole, and often six or eight, the source of profit is diminished or destroyed by several means; first, by using too much seed; and secondly because three or four grains springing out of one hole will not make such a strong plant or stand as one sound grain. In answer to these remarks, we are informed, that an agriculturist himself dibbled a great many holes, and dropped necessarily one, two, three, &c. to ten grains of wheat in each hole. He carefully gathered the wheat, and put the produce of all the one grain holes, and of the two grain holes, and of the three, and so on to the ten, upon one bushel the ten pecks, these holes which had three, four, and five grains were distinctly the heaviest produce; and he consequently concluded that three, four and five grains were the proper number to drop into each hole. To attempt dibbling either wheat or beans by hand on a large scale, we

consider quite suitable to the present improved state of agriculture; but it may sometimes happen, that on rich heavy land, especially in a showery season, there may be no other way of getting in the seed.

5035. The after-culture of wheat, or culture of the growing crop, depends on the manner in which it has been sown.

5036. When wheat is sown broadcast, the subsequent culture must generally be confined to harrowing, weeding, hand-weeding, or hand-hoeing with a pronged hoe. As great care is frequently given to sowing on winter-sown wheat, the harrows and rollers are employed to loosen the soil, and cover the seed. But these operations, to a certain extent, and at the proper season, are almost indispensable to the wheat crop itself, and are sometimes performed even when grain seeds are not to be sown. One or two courses of harrowing penetrate the crust which is formed on tenacious soils, and operate like hand-hoeing in raising a fresh mould to the stems of the young plants. Rolling is spring-coupled never to be omitted on dry porous soils, which are frequently left in so loose a state by the winter frosts, that the roots quit the soil and perish; and, if the land is rough and cloddy, the roller has a still more beneficial effect than the harrows in pulverising the most masses, and extending the pasture of the plants. Hand-weeding, so far as to cut down thistles and other long weeds, is never neglected by careful farmers, but the previous culture ought to leave as little as possible of this work to be done when the crop is growing. (See p.)

5037. Where wheat has been drilled, ridged, or drilled, the underbills may be hoed or stirred either by hand hoes, common or pronged, or by horse-hoes or drill harrows. In general, the drill used at sowing will, by the changes it admits of in its double character of drill and horse hoe, be the best to use for hoeing or stirring; or if a single drill should have been used, the expanding horse-hoe, or Wilkie's banks harrow may be successfully adopted. The operation of hoeing or stirring should generally be performed in March and need not be repeated. When grass-seeds are to be sown among the wheat the horse is an excellent mode of covering them. Weeding the rows should not be neglected, nor delayed later than the beginning of June.

5038. Where wheat rises too thick in some places, and too thick in others, whether in rows or broad-cast, the practice of transplanting from the thicker to the thinner has been recommended. This is said to be practised occasionally in Essex and Norfolk, and the time is the end of March. To be attended with success the soil must be in a good state and the blanks to which the plants are to be transplanted must be stirred up with a trowel or small two pronged fork. Under such circumstances we have no doubt of the plan being attended with success; but we are certain that without stirring the soil, the operation will not pay for the expense. Blanks are sometimes filled up by sowing summer wheat, dubbing beans, &c. but these are obviously bad modes. A better is either to stir the soil well, by the hand pronged hoe, and encourage the tillering of the plants, or to stir the soil and then transplant.

5039. Top-dressing wheat crops has been recommended in cases where the land is not in a sufficient state of fertility or preparation to bring the crops to perfection. Substances of both the solid and fluid kinds have been made use of for this purpose. The first consists chiefly of the dung of different sorts of birds, after being brought into a powdery state; bone-dust, scot, peat ashes, and various saline matters. The latter are principally the drainings of dung-hills and similar liquid materials. The former should be thinly sown over the crop with as much evenness as possible, as early in the spring as horses can be admitted upon the land without injury; and if it can be done when the weather is inclined to be moist, it is the better a roller may then be passed over the crop with advantage. When the latter substances are made use of, care should always be taken that the plants be not injured by having too large a quantity applied to them. In this practice the expense should be a primary consideration, and small trials first made where dungs have not been used. The proper season for performing the business is the beginning of February.

5040. When wheat appears too forward and luxuriant it is sometimes cut down in April with sheep or even with horses, but this requires great judgment to be effected without injuring the crop.

5041. In harvesting wheat the best farmers both of Britain and the continent agree, that it ought to be cut before it becomes dead ripe. When this is the case, the loss is considerable, both in the field and stack yard, and the grain, according to Professor Thaez, produces a less white flour.

5042. In ascertaining the proper state Brown observes, it is necessary to discriminate betwixt the ripeness of the straw and the ripeness of the grain for in some seasons, the straw dries upwards under which circumstance, a field, to the eye, may appear to be completely fit for the sickle, when in reality, the grain is imperfectly consolidated, and perhaps not much removed from a milky state. Though it is obvious that, under such circumstances, no further benefit can be conveyed from the root, and that nourishment is withheld the moment that the roots die yet it does not follow, that grain in such circumstances should be immediately cut; because, after that operation is performed, it is to a great measure necessarily deprived of every benefit from the sun and air both of which have greater influence in bringing it to maturity, so long as it remains on foot, than when cut down, whether laid on the ground or bound up in sheaves. The state of the weather at the time also deserves notice. For, in moist, or even variable weather every kind of grain, when cut prematurely, is more exposed to damage than when completely ripened. All these things will be studied by the skilful husbandman, who will also take into consideration the dangers which may follow were he to permit his wheat crop to remain uncut till completely ripened. The danger from wind will not be lost sight of, especially if the season of the equinox approaches; even the quantity dropped in the field, and in the stack-yard, when wheat is over-ripe, is an object of consideration. Taking all these things into view it seems prudent to have wheat cut before it is fully ripe, as less damage will be sustained from rotting in this way than by adopting a contrary practice.

5043. The mode of reaping wheat is almost universally by the sickle. When cut, it is usually tied up in sheaves, which it is better to make so small as to be done by hands the length of the straw than so thick as to require two lengths to be joined for bands. The sheaves are set up in stacks or stools, each containing in all twelve, or, if the straw be long, fourteen sheaves. In the latter case, two rows of six sheaves are made to stand in such a manner as to be in contact at the top, though in order to admit the circulation of air they are placed at some distance below; along this line two sheaves more are placed as a covering, the corn end of both being towards the extremities of the line. In a few days of good weather the crop is ready for the barn or stack-yard. In the stack-yard it is built either in oblong or circular stacks, sometimes on frames supported with gillies to prevent the access of vermin, and to secure the bottom from dampness, and as soon afterwards as possible the stacks are neatly thatched. When the harvest weather is so wet as to render it difficult to prevent the stacks from heating, it has been the practice to make funnels through them, a large one in a central and perpendicular direction,

and small *hatch* men to communicate with it. In the best cultivated countries the use of large barns for holding the crop is disapproved of, not only on account of the expense, but because corn keeps better, or is less exposed to damage of any kind, in a well-built stack.

5044. *The threshing of wheat, before machines for that purpose were introduced, was an arduous and difficult task. The expense was very considerable, whilst the severity of the labour almost exhausted the power of the strongest man, especially in unfavourable seasons, when the grain adhered pertinaciously to the ear, and could not, without difficulty, be completely loosened and removed. In such seasons, expense was the smallest consideration which influenced the husbandman, it was the quantity of grain unavoidably lost which occupied his attention and, as it appeared difficult to find out a remedy, most people considered it as an evil which could scarcely be avoided. In short, the loss was great in almost every case, but greater with wheat than any other grain. Every thing of this nature, however may be prevented, now that threshing machines are introduced, provided the feeder is careful, and proportion the quantity on the board to the strength of the impelling power. Wheat, in fact, is now the cleanest threshed grain, because the length of the straw allows it to be properly beat out before it passes the machine, which sometimes is not the case with short oats and barley. If horses are used as the impelling power, then feeding is necessary, otherwise the animals may be injured, but where wind or water is employed, the business of threshing is executed speedily, completely, and economically. (Brown.)*

5045. *In performing the operation, one man feeds the grain in the straw into the machine, and is assisted by two half-grown lads, or young women, one of whom pitches or carries the sheaves from the bay close to the threshing-stage, while the other opens the bands of every sheaf, and lays the sheaves successively on a small table close by the feeder, who spreads them evenly on the feeding stage, that they may be drawn in successively by the feed rollers, to undergo the operation of threshing. In the opposite end of the barn or straw-house, into which the rakes or sickens deliver the clean-threshed straw, one man forks up the straw from the floor to the straw-mow and two lads, or young women, build it and tread it down. In a threshing-machine, worked by water or wind, this is the whole expense of hand labour in the threshing part of the operation, and, as a powerful machine can easily thresh from two to three hundred bushels of grain in a working day of nine hours, the expense is exceedingly small indeed. Assuming two hundred and fifty bushels as an average of the work of these people for one day, and their wages to be nine shillings, the expense does not amount to one halfpenny for each bushel of grain. Even reducing the quantity of grain threshed to one hundred and fifty bushels, the easy work of a good machine of inferior size and power, the expense does not exceed three farthings the bushel. But the whole of this must not be charged against the threshing only, the grain being half-dressed at the same time, by passing through one winnowing-machine, which is always attached to a complete threshing-mill and where a second can be conveniently connected with it, as is commonly the case if the mill is of considerable power: the corn comes down nearly ready for market so that the threshing, dressing and building of the straw with the use of a powerful water-mill, will scarcely cost more than dressing alone when the flail is employed; after every reasonable allowance for the interest of money and the wear and tear of the machine.*

5046. *When grain is threshed with a machine worked by horses the expense is necessarily and considerably enhanced. One couple of effecting the larger quantity of work already calculated on, will require eight good horses, and a man to drive them, who may perhaps require the aid of a boy. The value of the work of eight horses for a day cannot be less than forty shillings, and the wages of the driver may be added two shillings and sixpence. Hence the total expense of threshing two hundred and fifty bushels will amount to £1. 2s. 6d.; or about two-pence per bushel, when the wages of the attendants are added, still leaving a considerable difference in favour of threshing by the machine, in preference to the flail. Where it even occurred that the expense of threshing by horses and by the flail is nearly the same, horse-mills are to be recommended on other accounts such as better threshing, expedition, little risk of galling, &c.*

5047. *The produce of wheat must of course vary, according to the soil, climate, culture, and kind grown. Professor Thier says, that in general it gives double the weight of straw that it does of grain, on elevated grounds something less; and on low grounds something more. The yield of grain in some seasons has been under twenty while in others it is upwards of thirty bushels the acre, the soil and culture being in every respect the same. The average produce of Britain has been estimated at three, three and a half, and four quarters, and one of the largest crops ever heard of, at ten quarters, and the least at one quarter and a half. The proportion which the corn bears to the straw in Middlesex, is eleven and a half bushels to a load of thirty-six trusses of thirty-six pounds each, or eleven and a half cwt.; no great deviation from Professor Thier's general estimate, a bushel of wheat weighing about 60 or 61 pounds.*

5048. *To judge of a sample of wheat, examine by the eye if the grain is perfectly fed or full, plump and bright, and if there is any adulteration proceeding from sprouted grains, must, or the seeds of weeds; and by the smell, if there is any improper impregnation, and if it has been too much heated in the mow or upon the kiln; and finally by the feel, to decide if the grain is sufficiently dry, as when much loaded with moisture it is improper for the use of the miller and baker. In cases where a sample handles coarse, rough, and does not slip readily in the hand, it may be concluded not to be in a condition either for grinding or laying up for keeping. When millet and wild chamo-mile abound among the wheat crop, are reaped with it, and undergo fermentation in the sick, the grain will have the flavour of these strong smelling plants. To detect this in the sample, hold the grain close in the hand, moisten it with the breath, and then smell or taste it. This is the practice at Loughborough and other markets in Bedfordshire.*

5049. *The yield of wheat in flour is, on an average, thirteen pounds of flour to fourteen pounds of grain. In the chemical analysis of wheat, Sir Humphrey Davy found that one hundred parts of good full-grained wheat, sown in autumn, yield of starch seventy seven, and of gluten nineteen one hundred parts of wheat, sown in spring, seventy of starch, and twenty-four of gluten. American wheats he found to contain more gluten than the British; and, in general, the wheat of warm climates to abound more in gluten and in insoluble parts, and to be of greater specific gravity, harder, and more difficult to grind.*

5050. *The uses of wheat in the baking, culinary, and confectionary arts are well known. It is also used for making starch, by steeping the grain and then beating it in hempen bags. The mucilage is thus mixed with the water produces the acetous fermentation, and the weak acid thus formed renders the mudlage white. After settling, the precipitate is repeatedly washed, and then moulded into square cakes and kiln-dried. In drying, the cakes separate into flakes, as in the starch of the shops. Starch is soluble in hot water but not in cold; and hence, when ground down, it makes an excellent hair powder. Its constituents are carbon, 45.55, oxygen, 49.68 and hydrogen, 6.77 = 100.*

5051. *The uses of wheat straw are various and well known. As fodder it is, according to Professor Thaez, the most nourishing of any and it makes the best thatch it is generally preferred for litter, though rye and barley straw are softer. It is used for making bee-hives, horse collars, mattresses, huts, boxes, baskets, and all kinds of what is called Dunstable work, for the cider press and among other things, for burning, to procure potash from the ashes. The straw of wheat from dry chalky lands is manufactured into hats for both men and women. For this purpose, the middle part of the tube, above the last joint, is taken and, being cut into a length of eight or ten inches, is split in two. These splits are then plaited, by females and children, into various kinds of plait or ribbands, from half an inch to an inch broad. These, when sewed together according to fancy or fashion, form different descriptions of ladies bonnets, and the commoner plait and corner straw of men's hats. The hats are whitened by being placed in the vapour of sulphur. Leghorn hats are made from the straw of a bearded variety of wheat, which some have confounded with rye. It is cultivated on the poorest sandy soils in the neighbourhood of the Arno, between Leghorn and Florence expressly for this manufacture. It is of humble growth, and not above eighteen inches high. It is pulled up when green and bleached white by spreading and watering on the gravelly banks of the Arno. The straws are not split but in other respects the manufacture into ribbands is the same as at Dunstable in England and in the Orkney Islands.*

5052. *The Leghorn manufacture of wheat straw into the well-known hats has lately been enquired into, and detailed in several publications. The variety of wheat cultivated in Tuscany for this purpose is known as the *grano marzotto*, or *marzotto*, a variety of summer wheat with long bearded ears. It is cultivated on the sandy hills on both sides of the valley of the Arno. The seed is sown in March very thick, and pulled when the ear is fully shot, but before the grain is formed. It is then 18 inches high if the crop is good. It is bleached as we do flax, and afterwards tied up in bundles in the same manner and carried home, to have the part between the ear and the first joint in the stalk selected, that being the only part used. (*Gard. Mag.* vol. v. p. 70.)*

5053. *To obtain the whiteness so much prized, the straw is smoked with sulphur previously to being worked; the plait is also smoked; and, lastly the hat. About Semma the process is simply a little sulphur set on fire in the bottom of a large chest, bunches of the straw being placed on long hand rods across, and the lid shut down. Elsewhere the articles are described as being placed in a small close room in which a chafing dish of sulphur is placed, and set fire to. Sometimes the operation requires to be done twice before it succeeds.*

5054. *The straw for use is cleaned or stapled like our wool. Children or inferior hands work the coarse thick straw while good hands work the fine only. Whether fine or coarse, it is only the part on which the spike grows that is made use of; and it is always the same plait, consisting of thirteen straws, which is worked. In the fine plait there is a very great waste of straw, as they reject all that is in the least too thick, and they cut off a considerable part of the straw when it comes near the flower-spike. Fine plait is not accounted good unless very much drawn together; for which end it is worked very wet. The bunches of straw are always put into a small jar, filled with cold water which stands beside the worker. After being soaked and pressed, the plait is made up into hats by women, who do nothing else; it is not put together by edges, nor overlapped. On the operation of pressing a great deal depends; there are only two good machines for that purpose in the country. Such is the practice for growing the hat straw what they sow for seed is in other ground, not one fourth of the seed is used, and the grain is allowed to come to maturity in the usual way. It is said to be a capital wheat for variegated, macaroni, &c. and also for making into bread. (*Gard. Mag.* vol. v. p. 71.)*

5055. *The introduction of the grano marzotto into Britain has been tried, but not attended with success. Messrs. J. and A. Muir, after various trials, found the straw of rye preferable.*

5056. *The mode of stapling is as follows:—The straws being picked, and put into separate bundles, according to their quality, let thirteen of them be taken and tied firmly together by the root ends; stretch them to any thing such as the back of a chair, to keep them steady; then take hold of the loose end of the bundle, putting six straws into the one hand, and seven into the other. Take the outermost, and with it cross over two, then carry it behind the next two; and lastly before the remaining two; after which lay the straw into the other parcel of six. The first parcel of six being now made seven, take the outermost straw of it, and carry it across the bundle, by two, as in the former case, laying at last this seventh straw into the other parcel as before. It will be understood by this, that the outermost straw of each parcel is always made the acting straw and that, in the progress of the operation, each of the straws of each parcel is thus employed in its turn.*

5057. *As the work goes on, it will be necessary now and then to join in new straws. Being any one needing to be removed, watch until it becomes the acting straw; and when it is to be laid into the other parcel, after performing its round, lay it up over the place of plait, instead of putting it into the*

plaited as usually used in plaiting it by in a new straw, which is then to be used exactly as if it were the old one.

5055. If by chance, in working, any of the straw should break, a thing which can scarcely happen with vigilance to any but the most expert straw, and so it only through want of attention, it may be remedied without any more trouble than putting in a new one in its place; and though the outside of the plait with the old and new straw should exhibit the appearance of a broken loop, yet, in the knitting up of the work, it can easily be so managed that the defect shall be entirely concealed.

5056. The finishing need not be begun till as much of the plait is made as may be supposed sufficient to form a hat, as an entire hat of any desired shape may be made up of a single piece of plait. About 70 or 80 yards will be sufficient to make a lady's hat.

5057. Outside and inside of the hat. In joining in new straw during the plaiting, the ends of the new and old having been kept on the upper side of the plait, this will therefore be made the inside of the hat. After finishing and turning the plait a little, to make it form the round place for the top, the plait will be found to lie with the one side to the other. Like the teeth of two saws turned in each other and then so to make these two opposite sides that they may present the appearance of one piece, begin to sew by putting the needle in through the sort of stitch or loop on the outside of the plait, inserting the needle from below. Take the stitch of the opposite piece in exactly the same way and, after four or five stitches of each side are taken on the thread, draw it up tightly so that the stitches of both may be brought fairly the one beside the other. In this manner in the covering of the operation, it will soon be seen that the place where the seam is can scarcely be discovered from the rest of the plait.

5058. To sew the crown of the hat so that it may be quite plain, every stitch of the one side must not be taken with every one of the other, but every second or third only of one of the sides, till the work get on a little.

5059. The blocking of a hat may be done with any round piece of smooth stick that will fill it. After the hat is well shaped, and put on the block, it may be made quite smooth by beating it gently with a hammer. (*See Jour. Ag. vol. i. p. 504.*)

5060. The diseases of wheat are the rust, smut, or black mildew, the latter including what is vulgarly called blight. These have been already treated of in our view of the vegetable economy, and we shall merely offer a few practical observations on the smut and mildew.

5061. The predominant cause of smut, in whatever manner the seed may be transmitted from the seed pickle to the ground to the ear, is, some certain, is in general the infection of the seed by the dust of the smut-bill, which R. de Jussieu first conjectured to be *Lycopodium globosum*, and which M. Favonius ascertained to be a microscopic vegetable of some sort and that though the most careful washing, even with the application of caustics, may not in every case insure against smut, yet if the seed be prepared in the way already mentioned, the disease will never prevail to such a degree as to affect materially the value of the crop. This is all that cultivators need to know, and all, perhaps, in the present state of science, that can be known, of the cause and prevention of smut. See an article at length on this subject in the *British Farmer's Magazine*, vol. III. p. 176.

5062. Mildew is a much more destructive distemper than smut; and, as it is probably occasioned by a peculiar state of the atmosphere during the periods of flowering and ripening, it is likely to befall all seasons at prevention. The prevalence of heavy fogs or mist, drizzling rains, and sudden changes in the temperature, have been assigned as the causes of mildew, and as it has been found that open airy exposures are much less affected than low sheltered lands, in years when mildew prevails most generally the disease may perhaps be somewhat diminished by drilling, which admits a free circulation of air. Spring or summer wheat is less liable to mildew than the winter species, though it does not always escape. Minute parasitical fungi, *Erysiphe Graminis* (Sw. of *Puccinia*), are commonly detected on the straw of mildewed wheat, and these cannot be the least doubt that the history bears, and probably several other species on which these fungi abound, have a powerful influence in communicating the disease to a certain distance. (*See Joseph Smith on Mildew, and Com. to the B. of Ag. vol. vii.*)

5063. The wheat fly has, of late years, been one of the greatest enemies to the wheat crop in Scotland. In North America this insect, or one of the same family, has been known for many years, more especially in New England; and its alarming ravages are depicted from time to time in the newspapers, under the name of the Hessian fly. In the modern nomenclature, the Rev. W. Kirby informs us that the wheat fly, formerly the Hessian fly, is now the *Cecidomyia tritici* (*Ag. 796. c.*) and the Hessian fly the *C. destructor* (b). The wheat fly generally makes its appearance about the end of June; and, according to the observations of Mr. Shireff, they exist throughout a period of thirty-six days. The first of the fly is orange, the wings transparent, and changing colour according to the light in which they are viewed. It lays its eggs within the glumes of the flower, in clusters varying in number from two to ten, or even fifteen; and the larvae feed upon the grain. "They are produced from the eggs in the course of eight or ten days: they are at first perfectly transparent, and assume a yellow colour in a few days afterwards. They travel not from one flower to another, and forty-seven have been numbered in one. Occasionally there are found in the same flower larvae and a grain, which is generally shrivelled, as if deprived of nourishment; and although the pollen may furnish the larvae with food in the first instance, they soon crowd round the lower part of the germs, and there, in all probability, exhaust on the matter destined to form the grain." (*Mag. Nat. Scot. vol. ii. p. 450.*) The larvae are preyed on by the Chalcidion destructor, an ichneumon fly, which deposits its eggs in the body

of the larvae of the wheat fly; and this is the only check hitherto discovered for preventing the total destruction of the wheat crop attacked by the *Cecidomyia*. Mr. Shireff, speaking of the ichneumon, says, "I could not determine if it actually deposits its eggs in the maggot's body but there can be no doubt, however, of the ichneumon piercing the maggot with a sting; and, from stinging the same maggot repeatedly, it is probable the fly deposits to destroy the maggot, as well as to deposit eggs in their bodies. The evening, also, deposits the maggot as food." (*Brit. Fern. Mag. vol. III. p. 458.*) Mr. Gervie estimates the loss sustained by the Hessian fly in the County of Galloway district alone, by the wheat fly at £10,000 in 1857, at £3,000 in 1858, and at £5,000 in 1859. (*Scott. Agricult. vol. i. p. 45.*) The same writer, in May 1859, thus depicts the prospect of the wheat crop in the County of Galloway:—"The *Cecidomyia* are still alive in formidable numbers. That the Hessian fly causes as little or great plenty as ever is now quite certain; that they will lay their eggs on no other plant than those of the wheat genus is also true; the only chance of success is in the time they come, and the weather. Should the early weather bring them forward with a drizzle or shower within this date, the greater part will have perished before the wheat is

in the ear, or should the cutting take place before the spike appears, then only the late or spring-sown wheats will suffer; but these appear slender chances. We know the history and habits of the insect too well to believe that either mist, or rain, or dew or drought, will either forward or retard their operations, if the main body appear about the time the wheat comes in the ear. In addition to that vile grub, our neighbours in the *Lochians* are threatened with a no less formidable invader in the *A. scius pumilio*, *scius*, which, as we are informed on respectable authority have already commenced their depredations, and are detaching the wheat plants rather liberally in that quarter. It, like the *Heusler* of St. America, attacks the under joint, which becomes habitations for the young larva. As far as our observation extends, this pest has not yet reached us in noticeable numbers." (*Cornwall Times*, May 17 1856.)

5067. The culture of summer wheat differs from that of winter or spring-sown winter wheat, in its requiring a more minutely pulverised and rather richer soil. It need not be sown sooner than April, and it advances so rapidly to maturity that it hardly affords time for hoeing (if sown in rows), or harrowing and rolling. When grass or clover seeds are sown on the same ground, they are sown immediately after the wheat, and harrowed in with a light harrow or rolled in. In this respect, and indeed in all others, the preparation of the soil and sowing of this grain are the same as for barley.

5068. The produce of summer wheat both in grain and straw, is considerably less than that of winter wheat the straw is only fit for litter or inferior fodder the flour produced by the grain is rather coarser and darker than that of common wheat. Of course this sort of wheat cannot, as already observed, be recommended for general culture.

SECT. II. *Rye*. — *Secale cereale* L. *Tridentaria Dufroya* L., and *Gramineae* J. *Seigle*, Fr., *Rogon*, Ger., *Segale*, Ital., and *Centeno*, Span. (fig 725)

5069. *Rye*, according to some, is a native of *Crete*; but it is very doubtful whether any country can be now ascertained to be its native soil. It has been cultivated from time immemorial, and is considered as coming nearer in its properties to wheat than any other grain. It is more common than wheat on most parts of the continent, being a more certain crop, and one which requires less culture and manure. It is the bread corn of Germany and Russia. In Britain it is now very little grown, being no longer a bread corn, and therefore of less value to the farmer than barley, oats, or peas. Many consider it the most impoverishing of all corn crops.

5070. The varieties of rye are not above two, known as winter and spring rye; but there is so little difference between them that spring rye sown along with winter rye can hardly be distinguished from it.

5071. The soil for rye may be inferior to that chosen for wheat it will grow in dry sandy soils, and produce a tolerable crop and, on the whole, it may be considered as preferring sands to clays. The preparation of the soil should be the same as for wheat. According to Professor Thaer, rye abstracts 30 parts in 100 of the nutriment contained in the soil on which it is grown.

5072. The climate for rye may be colder than for wheat but it is rather more injured by rains during winter, and equally injured by moist weather during the flowering season.

5073. *Rye* is sown either in autumn or spring, and either broad-cast or in drills two bushels and a half is the usual allowance when it is sown broad-cast. As it vegetates more slowly than wheat, it should be sown when the soil is dry a wet soil being apt to rot the grain before it has completely germinated. No picking or other preparation is given.

5074. The after culture, harvesting, and threshing are the same as for wheat and the produce in grain is, under similar circumstances, equal in bulk but in straw it is greater in rye than in any other grain. Sir H. Davy found, in 1000 parts of rye, 61 parts of starch and five parts of gluten. Professor Thaer says rye is the most nourishing grain next to wheat. It contains an aromatic substance, which appears to adhere more particularly to the husk since the agreeable taste and smell peculiar to rye bread are not found in that which is made from rye flour that has passed through a very fine bolting-cloth; while the fragrance may be restored by a decoction of rye bran in the warm water used to make the dough. This substance, Thaer says, seems to facilitate digestion, and has an action particularly refreshing and fortifying on the animal frame.

5075. The use of rye is chiefly for bread, especially for gingerbread. It is also used in the distilleries and the straw is used for the same purposes as that of wheat, except that it is useless as fodder. Some prefer it for thatching and litter and also for collar-making it is also employed in Dunstable work. Tanners are said to use it in some districts.

5076. *Rye* is sometimes sown as a green crop, with a view of affording some keep for sheep early in the spring, and also for being ploughed in as manure, but that husbandry

must be full of unfortunate which requires recourse to either mode. In some districts it is customary to sow the head lands of wheat fields with rye, which is said to keep poultry from penetrating to the wheat.

5075. The manufacture of rye straw hats *plat for hat* is a new application, for which the public are indebted to Messrs. Z and A. Blair of Greenock, manufacturers of straw hats in imitation of those of Lombardy. Women have long previously used rye grass, crested dog's-tail grass, erect-stemmed vernal grass, and the straw of wheat, raised both from British and foreign seeds, without success. At last the idea of employing rye straw was suggested to them, and they now send annually to their establishment in the Orkney Islands (purchased by an English gentleman about 1830) "from 40 to 45 bolls, which are sown on about twelve English acres of sandy soil, manured with sea-weed. Several acres of heath for bleaching the straw, and water for steeping it, are required in the neighbourhood of the rye fields. The rye is cut when the seed is beginning to form, and it is necessary to attend to the rippling time, for ten days too early or too late produce a considerable difference in the loss of the straw. When the rye is cut, women are employed to tie it at the lower extremity in handbills; it is then put into boxes, and covered with boiling water, in which it remains for half an hour. After this it is spread out upon the heath in a fan form, and turned twice daily until the bleaching, which takes about ten days, is completed. If exposed to much sun while bleaching, the straw is injured in colour, and rendered very liable to take mildew. It is of great importance to have the crop well housed.—"The seed of the rye is sown in April, in moor ground, recently rendered arable, and if the season is at all favourable, it comes into flower in July when it is cut down. The whole stem is then immersed in boiling water in a trough made for the purpose, and remains in this state for two hours. When taken out, it is spread upon a grass field, and exposed to the sun, till it is perfectly bleached, which requires from two to four days, according to the weather. When bleached, the stalk is divided into separate parts at each joint, and put up into bundles by the length. In this manner the bundles lie in a proper place till wanted by the platform. This last process is done chiefly by old people, who are unable for the finer work, or by those people who have only lately joined the manufactory. (Trans. Highland Soc. vol. vi. pp. 260. and 261.) The mode of plating has been already described. (3) 5086.)

5078. Rye is less subject to disease than most other grain, and is even sown among wheat and round wheat fields from an idea that it will keep off blight and mildew as well as poultry.

5079. The spur or ergot of rye is by some considered as a fungus, a species of *Sclerotium*, somewhat analogous to those which are the cause of the rust. It is not peculiar to rye, but is very common in many other grasses and plants. "It is a production of the seeds, is long, horny and cartilaginous, and is sometimes straight, at others curved, sometimes it is found more than two inches in length. The resemblance of this substance to cooks' spurs has given it the name by which it is distinguished. On breaking a spured seed, you find within it a substance of a dull white colour adhering to the viscid skin that surrounds it. Rye does not attack constant germinals. M. Tassier remarked that the most rainy years were the most productive of this disease, that the seeds on which most spured rye grew were most moist; that high grounds were nearly free from them, unless when the furrows prevented the water from running freely off, while the lower parts of the same field produced more than the upper parts." (*Brit. Farm. Mag.* vol. vi. p. 322.) In France a disease, called the chronic or dry gangrene, has been produced by sowing ergot. This disease is also known in Switzerland, where it was observed that most animals refused to eat diseased rye, or rye affected with the ergot, as it is called. The Royal Society of Medicine at Paris employed M. Tassier, a distinguished agricultural writer and man of science, to go into the countries where the dry gangrene prevailed, and collect a sufficient quantity of the ergot or cockspur rye for experiments. The result confirmed the opinion of those who attributed the disease to the cause assigned. "France afforded, also, a simple explanation of the fact that persons might live for a considerable time upon rye affected with the cockspur without suffering any sensible injury from its use; since, in all the animals upon which it was tried experimentally a given quantity was required to produce the specific effect; and they suggested the only measure, that of separating the diseased from the sound rye, which could prevent so great a national calamity as that which has been so often produced by its use. The spured rye occasionally occurs in this country but there are no instances recorded of its producing any such effects as it is said to do in France. But in the *Philosophical Transactions* Dr. Wollaston has narrated several cases in which dry gangrene was produced in one family by partaking of diseased wheat and nearly the same effects were produced in a family in Wiltshire by the *Lilioid* manure containing largely into the composition of bread. (*Stephenson and Churchill's Med. Bot. art. Secale*.) M. Lapeyron states that the ergot is covered with a thin pellicle and filled with a grey powder. It is collected in Spain by women and children, who wade in the fields of standing rye for the purpose, and with their utmost vigilance can obtain it but in very small quantities, in consequence of which it sells high as an article of the modern medicine. (*Brit. Farm. Mag.* vol. vi. p. 128.) Medicinally it is used in uterine diseases.

Sec. III. Barley. — *Hiridrum L.* *Triticum Dignia L.* and *Grommea J. L'Orge, Fr.* *Gerste, Ger.* *Orzo, Ital.* *Byg, Dan.* and *Swed.* ; and *Cebada, Span.*

5080. Barley, though less calculated for a bread corn than rye, may be considered as next in value to wheat in Britain. Of what country it is a native is unknown. Some ascribe it to Tertiary, others to Siberia, and even Scotland has been mentioned. It has been cultivated from the earliest antiquity and was much in use among the Romans, both as food for soldiers and horses. In Sweden and Lapland it is more cultivated than any other grain, on account of its requiring to be so short a period in the soil; sometimes not longer than six weeks, and seldom more than seven or seven and a half. In Spain and Sicily they have two crops a year on the same soil: one is sown in autumn and ripens in May, and the other is sown in May and reaped in autumn. In Britain barley is a tender grain, and easily hurt in any of the stages of its growth, particularly at seed time: a heavy shower of rain will then almost ruin a crop on the best prepared land, and in all the other processes greater pains and attention are required to insure success than in the case of other grains. The harvest process is difficult, and often attended with danger; even the threshing of it is not easily executed with machines, because the corn generally adheres to the grain, and renders separation from the straw a troublesome task.

5081 *Species and varieties.* (Ag. 795.) There are six species and subspecies of this grain in cultivation besides varieties. These are,—

- |   |   |
|---|---|
| 1. <i>Holcus vulgare</i> , Spring barley (a).<br>2. <i>Holcus vulgare</i> , Winter barley.<br>3. <i>Holcus vulgare</i> , Winter barley (b). | 4. <i>Holcus distichus</i> , Common or long-eared barley (c).<br>5. <i>Holcus distichus</i> , Naked barley.<br>6. <i>Holcus distichus</i> , Sprat or beardless (d). |
|---|---|

The second and fifth sorts are allowed to be subspecies or varieties of the first and fourth, and indeed there can be little doubt that the whole do not constitute more than one species.

5082. The spring barley or early barley (a) *Orga cereale Sacrum de printemps* Fr., is distinguished by its double row of beards or awns standing erect, and its thin husk, which renders it favourable for malting. This is the sort principally cultivated in the southern and eastern districts of both England and Scotland, and of which the farmers make two sorts, viz. the common, and the rath-ripe barley but these two sorts are in reality the same for the rath-ripe is only an alteration of the common barley occasioned by being long cultivated upon warm gravelly soils. The seed of this, when sown on cold or strong land, will, the first year, ripen near a fortnight earlier than the seed taken from strong land, and therefore the farmers in the vales generally purchase their seed-barley from the warm or gravelly lands; for when preserved in the vales two or three years, it becomes full as late in ripening as the common barley of their own product on the other hand, the farmers on warm lands are also obliged to procure their seed-barley from the strong lands, otherwise their grain would degenerate in bulk or fulness, which by this change is prevented.

5083. The *Marston barley* *Orga celestis*, Fr. and *Hemel grove*, Ger. is a variety of early barley with broader leaves, and reckoned more productive than the other. It is much grown in the north of Europe, and was introduced to this country in 1768 but is believed to be now lost or merged in the parent species.

5084. Winter barley late barley or square barley (b) *Orga cereale d'hiver, Escourgeon*, Fr. has the grains disposed in four or six rows, large and thick skinned. It is chiefly cultivated in the north of England and in Scotland, on account of its hardiness but from the thickness of its rind it is ill adapted for malting, and is going out of use.

5085. Bigg hay, or barley big, is a variety of winter barley known by always having six rows of grains, by the grains being smaller and the rind thicker and by its being earlier than the parent variety. Professor Martyn says, he has frequently counted forty-two grains on one ear of bigg, when common or long-eared barley had only twenty two.

5086. Common or long-eared barley (c), is known by its very long spike or ear flatted transversely greater in breadth than thickness, with chaff ending in an awn sixteen times the length of the grain. This sort is cultivated in many parts of England and Scotland though some object to it because the ears being long and heavy they think it apt to lodge.

5087. Naked barley or wheat barley *Orga cereale a densa rumpo* Fr., is known by the grain separating easily from the chaff, and is by some considered as nothing else than spelt wheat, which it greatly resembles. It does not appear to be cultivated at present in any part of Britain.

5088. Sprat, or beardless barley (d) *Orga imbricat, Orga-cis*, Fr. is known by its low stature, coarse straw, short broad ears, and long awns. The long awns and coarseness of the ears protect it better from birds than most other sorts, but as the straw is coarse and of little use it is not much cultivated.

5089. Besides these sorts there are some local varieties as Thanet barley Putney barley &c. which are merely names given to the varieties common in those places. The Thanet is the winter and the Putney the sprat barley.

5090. New varieties may be procured by selection or crossing, as in the case of wheat. (5009.)

5091. In choosing a sort of barley for cultivation, regard must be had to the soil and climate. The hardiest may be considered the winter barley and the earliest, and perhaps the best, is the spring barley. The long-eared is also a much esteemed variety.

5092. In choosing from any particular variety the best grain for sowing is that which is free from blackness at the tail, and is of a pale lively yellow colour intermixed with a bright whitish one; and if the rind be a little shrivelled, it is so much the better, as it shows that it has sweated in the mow and is a sure indication that its coat is thin. The husk of thick-rinded barley being too stiff to shrink, will be smooth and hollow even when the flour has shrunk from it within. The necessity of a change of seed from time to time, by sowing that of the growth of a different soil, as it has been observed, is in no instance more evident than in the culture of this grain, which otherwise becomes coarser and coarser every year. But in this, as well in all other grain, the nearest care should be taken that the seed is full bodied.

5093. The best soil for barley is a light rich loam, finely pulverised. It will neither grow well on a sandy or soft soil, nor on strong clays, such as are suitable for wheat.

5094. The preparation of the soil is sometimes by a naked fallow, but generally by a turnip fallow; sometimes it is taken after peas and beans, but rarely by good farmers either after wheat or oats, unless under special circumstances.

**5095.** *When sown after winter crops* it is generally taken with one furrow which is given as that as the harrow is completed, the ground thus becoming much benefited from spring frosts. Just when time or space becomes necessary for the sowing of summer crops, however, upon a spring draught sowing, the surface, being covered by the removal or destruction of the crop, just as the soil is to receive a greater quantity of ploughing, harrowing, and rolling necessary than would otherwise be called for. When sown after winter crops, one winter and one spring ploughing are usually bestowed; but, when after wheat or oats, these ploughings are necessary so that the ground may be put in better condition. These operations are very difficult in a wet and backward season, and rarely in that state is the ground so well as it should be before. Where land is in such a condition as to require three ploughings before it can be sown with barley it is better to sow it at once, then to run the risk which seldom fails to accompany a quantity of spring labour. If the weather be dry moisture is lost during the different processes, and a frequent germination necessarily follows. If it be wet, the benefit of ploughing is lost, and all the evils of a wet seed-time are sustained by the future crop. (Brown.)

**5096.** The sowing of barley depends, the harrow and roller, when the plough alone is insufficient, should be employed in reducing the soil to a considerable degree of fineness. In most cases more than one sowing is given; though, after a winter furrow the grubber may be used in spring instead of the plough. After turning, sowing on the ground by sheep, the land, being consolidated by their treading, sometimes receives two ploughings, but, if only one, it should be well harrowed and rolled, and it is often finished by harrowing after the roller, especially if grass-seeds be sown, which are covered by this last harrowing. Barley is sometimes sown on the first ploughing, and covered by a second shallow ploughing. As it is found of great importance, with a view to speedy and equal vegetation, that the ground should be such and moist, barley is generally sown upon what is termed *set-fer*; that is, as soon as possible after it is turned up by the plough.

**5097.** *Manner* can seldom be given with advantage to a crop that occupies the soil so short a period as barley and therefore it generally is sown on land which has been enriched for a preceding crop.

**5098.** *The climate* in which barley delights is warm and dry. There are instances of a crop being sown and ripened without having enjoyed a single shower of rain but gentle showers from the time it is sown till it begins to shoot into the ear, are favourable; while heavy rains at any period, and especially immediately after sowing, or during the blossoming, ripening, and reaping seasons, are highly injurious.

**5099.** *The best season for sowing barley* is considered to be from the beginning of April to the middle of May but bigg may be sown either in autumn to stand the winter, or as late as the first week of June. In England, the winter or four-rowed barley is frequently sown in autumn, and stands the most severe winters. With respect to the lateness at which bigg and summer barley may be sown, much depends on the sort of weather which occurs during the first three weeks after sowing.

**5100.** *When barley is sown late* it is sometimes steeped in common water to promote its germination; but it is seldom putrid or otherwise prepared. The advantages of steeping are, procuring an equal germination, and consequently ripeness, and retarding the start of weeds. The following directions are given for performing the operation. — First, take out about one-third of the contents of the sacks of seed barley or heat to allow for the swelling of the grain; lay the sacks with the grain to steep in clean water; let it be covered with it for at least twenty-four hours when the ground is very dry, and no likelihood of rain for two or three days, it is better to be thirty-six hours. Sow the grain wet from steeping without any addition. The seed will either swell as clean water has no tenacity, only the cover must put in a furrow or a third may be sown in bulk than is usual of dry grain, as the grain is swelled in that proportion. Harrow it as quickly as possible after it is sown and though not necessary give it the benefit of a fresh furrow if convenient. You may expect it up in a fortnight at furthest. (Brown.)

**5101.** *The quantity of seed* is different in different cases, according to the quality of the soil and other circumstances. Upon very rich lands, eight pecks per acre are sometimes sown; twelve is very common; and upon poor land, more is sometimes given.

**5102.** *Whether the practice of giving so small a quantity of seed to the best lands is advantageous or the reverse,* seems a disputed point among the best farmers. That there is a saving of grain there can be no doubt and that the bulk may be as great as if more seed had been sown, there can be no little question. Little argument, however, is necessary to prove that this sowing of barley must be attended with considerable disadvantages. For if the early part of the season be dry, the plants will not only be stunted in their growth, but will not stand out offshoots and if rain afterwards fall, an occurrence that must take place some time during the summer often at a later period of it, the plants begin to stool, and send out a number of young shoots. These young shoots, unless under very favourable circumstances, cannot be expected to arrive at maturity; or if their ripening be wasted for, there will be a great risk of losing the early part of the crop, a consequence that frequently happens. In almost every instance an unequal sample is produced, and the grain is far the most part of an inferior quality. By good judge, it is thought preferable to sow a quantity of seed sufficient to secure a full crop, without depending on its sending out offshoots. Indeed, where that is done, few offshoots are produced, the crop grows and ripens equally and the grain is sufficiently good. (Brown on Rural Affairs.)

**5103.** *The modes of sowing barley* are either broad-cast, or in rows by the drill or ribbing. The broad-cast mode is almost universally adopted; unless in lands much infested with annual weeds, where drilling and hand-hoeing, and in particular cases horse-hoeing, may be employed with advantage.

**5104.** *The only culture which barley requires while in a growing state, is hoeing and weeding* if in rows, and weeding alone if broad-cast. Sometimes barley is rolled to compress a soft soil and exclude the drought, and when very thick it may be first harrowed and then rolled. Grass seeds and clover are sown with the grain before the last harrowing, when the broad-cast mode is adopted; and immediately before hoeing, when the barley is in rows. The former is much the best mode for insuring a strong plant of clover.

**5105.** *Rolling down barley,* which from winter or very early sowing is over-luxuriant, is practised in some districts, but it is alleged that mowing is much better than rolling it; because the scythe takes off only the rank tops, but the steep seed tops all indifferently; nor should they even, in any case, be lost

green it has been, between being particularly firm of the shoot and of the stalk next the root, they rise as they go to support the future growth of the plant.

5106. *Barley is ripe when the red soon, as the farmers term it, meaning a reddish colour on the ear, is gone off; or when the ears droop, and fall, as it were, double against the straw, and the stalks have lost their verdure but in the latter case it is too ripe.*

5107. *In the harvesting of barley more care is requisite than in taking any of the other white crops, even in the best of seasons, and in bad years it is often found very difficult to save it. Owing to the brittleness of the straw, after it has reached a certain period it must be cut down; as, when it is suffered to stand longer, much loss is sustained by the breaking of the heads. On that account it is cut at a time when the grain is soft, and the straw retains a great proportion of its natural juices, consequently requires a long time in the field before either the grain is hardened or the straw sufficiently dry. When put into the stack sooner it is apt to heat, and much loss is frequently sustained.*

5108. *Barley is generally cut down in England with the cradle scythe, and either tied up or carted home loose after lying in the swath some days to dry. It is not apt to shed but in wet weather it will be likely to spoil or grow musty, and therefore every five days after rain it should be shaken up and turned and when it is tolerably dry let it be made up into shocks but be careful never to leave it till thoroughly dry lest it more burn, which will make it make worse than if it had sown in the field. It is remarked by Lusk that poor thin barley should be cut a little sooner than if the same plants were strong and vigorous, as the straw when the plants are full ripe, in such cases will not stand against the scythe. In this situation, barley is particular should be in swath till it is thoroughly dry. Some of his barley which lay out in swath five or six days in very fine weather though both blighted and edge-grown grew plump, and acquired very near as good a colour as the best. He reckons short scythes the best for mowing lodged or crumpled corn, because they must the fastest plants and observe, that a bow upon the scythe, which carries away the swath before it, is preferable to a cradle, the fingers of which would be pulled to pieces by the entangled corn, in drawing back the scythe. In Scotland and Ireland it is generally reaped with the sickle, bound in sheaves, and set up in shocks.*

5109. *In stacking barley many farmers make an opening in the stack from top to bottom. This opening is generally made by placing a large bundle of straw in the centre of the stack, when the building commences, and in proportion as it rises the straw is drawn upwards, leaving a hollow behind which, if one or two openings are left in the side of the stack near the bottom, insures so complete a circulation of air, as not only to prevent heating, but to preserve the grain from becoming musty.*

5110. *The threshing and dressing of barley require more labour than those of any other grain, on account of the difficulty of separating the awns from the ears. For this purpose some threshing machines are furnished with what is called a hummelling machine already described (3789) and where this is wanting, it is customary to put the grain, accompanied with a portion of threshed straw, a second time through the machine. Where barley has been mown, the whole of the straw requires to be twice threshed, independently of the necessity of getting rid of the awns.*

5111. *The produce of barley, taking the average of England and the south of Scotland, Donaldson considers, might be rated at thirty-two bushels but when Wales and the north of Scotland are included, where, owing to the imperfect modes of culture still practised, the crops are very indifferent, the general average over the whole will not probably exceed twenty-eight bushels the acre. Middleton states it as varying in England from fifteen to seventy-five bushels per acre. The average produce of the county of Middlesex, he says, is about four quarters of corn and two loads of straw per acre.*

5112. *The uses of barley are various. In Wales, Westmorland, Cumberland, and in the north, as well as in several parts of the west of Scotland, the bread used by the great body of the inhabitants is made chiefly from barley. Large quantities of the barley cultivated in England are converted into beer, ale, porter, and what is called British spirits, as English gin, English brandy, &c. The remainder beyond what is necessary for seed, is made into meal, and partly consumed in bread by the inhabitants of the above-mentioned districts, and partly employed for the purpose of fattening black cattle, hogs, and poultry. There is a much greater share of the Scotch barley consumed in distillation, in proportion to the quantity cultivated, than of the English. Exclusive of what is used for seed, the Scotch barley is either converted into beer or ale or made into pot-barley, or into meal, for the use of the inhabitants in the more remote and less cultivated parts of the kingdom or, lastly, into whisky. In *The Report of Middleton* it is stated, that much of the most ordinary barley is given to poultry: the rest is sold to the maltsters, except so much as is reserved for seed.*

5113. *But malt is the great purpose to which barley is applied in Britain. To understand the process of malting, it may be necessary to observe that the exsiccation of a seed, before a young plant is produced, are caused by the heat and suction of the earth into sugar and mucilage. Malting grain is only an artificial mode of collecting this by steeping the grain in water and fermenting it in heaps, and the arresting of its progress towards forming a plant by kiln drying, in order to take advantage of the sugar in distillation for spirit or fermentation for beer. The grain of barley contains starch and sugar and the chemical constituents of both these ingredients are very nearly alike. In the process of malting, a portion of the starch is converted into sugar so that the total quantity of sugar and consequently the mass of spirit, is increased by the transformation.*

5114. *To observe a proper sample of barley for malting, observe the directions given for choosing good barley (5091)*

5115. *Speltz barley* there are two sorts, *pearl* and *beak*; both are produced by grinding of the husk, and the *pearl barley* is produced by stripping the operation as far as to produce roundness in the head. It is used in soups, gruels, and medicinal drinks.

5116. *Barley* itself is ground like oatmeal or flour: the coarser sort, with the bran, is used for feeding by stock, especially pigs and poultry: but fine boiled barley flour, made into a thin porridge or pudding, and served cold in thick cakes, and dressed on a hot plate of metal, forms a light breakfast bread, which is common in some parts of Scotland. It is served in a moist state, hot, and served with butter and honey, and eaten in several fields. Two parts of barley flour, one of wheat flour, and one of rye, are said to make a light and very agreeable loaf of bread.

5117. The product of *barley* or *flour* is 13lbs. to 14lbs. of grain. Mr H. Davy found 1000 parts of barley meal to afford 990 parts of soluble or nutritious matter; viz. 790 of amylaceous or starch, 70 of sugar, and 60 of gluten.

5118. *Barley* straw is chiefly used for litter and packing; it is unfit for thatch or rope-making, and of little value as fodder.

5119. The diseases of *barley* are few, and chiefly want, but of quite a different species from that which afflicts the wheat, and one which it is found cannot be prevented by pickling and blanching.

SECT. IV The Oat. — *Avena sativa* L.; *Trifurcata* DufRoi L.; and *Graminea* J. L. *Avena*, Fr.; *Hafer* Ger.; *Fene*, Ital.; and *Avena*, Span.

5120. The oat is a very useful grain, and more peculiarly adapted for northern climates than either wheat, rye, or barley. Its native country is unknown, unless the wild oat be considered as the parent species, which is highly probable. The culture of the oat in France is chiefly confined to latitudes north of Paris. It is scarcely known in the south of France, Spain, or Italy, and in tropical countries its culture is not attended to. In Britain it has long been very generally cultivated, formerly as a bread corn, but now chiefly as horse-food. Of all the grain this is the easiest of culture, growing in any soil that admits of ploughing and harrowing.

5121. The varieties of oats are more numerous than those of the other grains, and some of them are very distinctly marked. The principal are as follows: —

5122. The white oat or common oat (Fig 757)

757

*Avena sativa* Fr., in most general cultivation both in England and Scotland, and known by its white husk and kernel.

5123. The black oat, *Avena elatior* var. *noir*, Fr. known by its black husk cultivated on poor soils, in the north of England and Scotland.

5124. The red oat, known by its brownish red husk, thinner and more flexible than, and firmly attached grain. It is early sown little from winds, made well, and suits windy situations and late climates. It is understood to have originated in Fife, on the estate of Magbiehill, by which name it is sometimes known.

5125. The Poland oat, known by its thick white husk, serviceable chiefly as a fodder grain, short white kernel, and short stiff straw. It requires a dry warm soil, but is very prolific. The black Poland oat is one of the best varieties; it sometimes weighs 50lbs. per bushel. It is, however, very liable to be shed by the wind after it begins to ripen; it requires a fine dry soil.

5126. The Friesian or Dutch oat, has plump, thin-skinned, white grains, mostly double, and the large one sometimes sown. It has longer straw than the Poland, but in other respects resembles it.

5127. The potato oat has large, plump, rather thick-skinned, white grains, double and triple, with longer straw than either of the last two sorts. It is almost the only oat now raised on land in a good state of cultivation in the north of England and south of Scotland, and usually brings

a higher price in the London market than any other variety. It was discovered growing in a field of potatoes in Cambridgeshire, in 1768; and from the produce of the single stalk which there sprang up by accident, probably from the mixture, has been produced the stock now in general cultivation.

5128. The Georgian oat, is a large, grained, remarkably prolific variety introduced from Georgia, by R. Barclay Esq. of Berry Hill, to Britain and the north of Europe. On rich soil in good till, Mr Barclay finds it yield more grain per acre than the potato oat or any variety whatsoever.

5129. The Siberian or Tartarian oat (b) is considered by some as a distinct species. The grains are black or brown, thin and small, and turned mostly to one side of the pedicle; and the straw is coarse and woody. It is little cultivated in England, but found very suitable for the poor soils and exposed situations on the sides of the English and Welsh hills.

5130. A variety called the winter oat, *Avena d'Hyver* Fr., has lately come into notice in some parts of England, but we have not been able to ascertain its origin. Mr Bennett of Chaxhill, near Gloucester sows two bushels per acre in October; finds the plants very luxuriant at Christmas, tillering like wheat; he sows them with oats and barley all the spring, and then sheds them up, and reaps an ample crop early in August. The grain is rather longer than that of the white oat, and the colour rather lighter than that of the black oat; Mr. Bennett received the seed from a friend in Massachusetts, who he conjectures received it from Russia, so that it is probably a recent importation. (Country Times, Feb. 8th, and Cor with Mr. Bennett.)

5131. There are other varieties, as Church's oat, the Angus oat, the Sun oat, &c., but they are either too local or obsolete to require particular notice. In the oat, as in other plants extensively cultivated, new varieties will always be arising from the plants of old ones.

5132. To procure new varieties adopt the mode by selection, by which, as it appears above, the potato and red oat were brought forward; or proceed systematically by cross impregnation, as directed for raising new varieties of wheat. Degenerney, Brown

observed, has taken place to a certain extent in the potato oat, but it is presumed that the consequences might be removed with ease, were first principles returned to. To make a selection of the strongest ears, which carried the purest grain, is not a difficult business, and were this selection attended to by half a dozen farmers in a district, it is obvious, that the breed, or variety, might be preserved pure and uncontaminated. If slovenly farmers were not provided with good seed, it would be their own fault; since, if they would not take the trouble to select and breed for their own use, they might always be provided by those who were either better qualified for making the selection, or were more attentive to the interests of agriculture. (Brown.) Some of the Northumberland farmers have been at the pains to select the grains, instead of the ears, after being threshed. The best seeds are picked out by hand by women.

5133. In choosing a sort from among the varieties described, the potato and Poland are the best for lowlands, and the red oat for uplands and late climates in a state of good cultivation. For inferior soils the white or common oat, and for the poorest of all the black oat, may be adopted.

5134. The soil for oats may be any land whatever, from the stiffest clays to moss or bog, provided it be laid sufficiently dry. The most tenacious clays, and meagre gravels and sands, where scarcely any useful seed-bearing plant, except buck-wheat, could be grown, will produce a crop of oats if ploughed at a proper season, and the seed judiciously sown and covered.

5135. The preparation of the soil for oats is less than for any other grain. It is almost always the first crop on newly broke-up lands, and as it prospers best on a soil not too finely pulverised, it is commonly sown on one earth. In regular rotations, oats are chiefly sown after grass, sometimes upon land not rich enough for wheat, that had been previously summer-fallowed, or had carried turnips after barley, and rarely after wheat, unless cross-cropping from particular circumstances, becomes a necessary evil. One ploughing is generally given to the grass-lands, usually in the month of January so that the benefit of frost may be gained, and the land sufficiently mellowed for receiving the harrow. In some cases a spring furrow is given when oats succeed wheat or barley, especially when grass-seeds are to accompany the crop. The best oats, both in quantity and quality are always those which succeed grass; indeed, no kind of grain seems better qualified by nature for foraging upon grass-land than oats; as a full crop is usually obtained in the first instance, and the land left in good order for succeeding ones. (Tron Affairs.)

5136. The climate for oats should be cool and moist when dry and warm the pendicles are so dried and contracted that they cease to convey sufficient nourishment to the ears, which thus never become plump, but thick husked, long awned, and unproductive in meal. This is very often the case with the oats in Scotland in a very dry year, and very common in the south of England in moist years.

5137. The season of sowing oats is from the last week in February to the end of April. About the middle of March is preferred by the best farmers. No preparation is ever given to the seed; but it should be plump, fresh, and free from the seeds of weeds. Common oats sown in autumn are generally killed during winter, the plant being in this respect more tender than wheat, rye, or barley bugg. In some parts of Ireland, and especially in the county of Dublin, the Friesland oat is sown in autumn and the advantage is they ripen nearly a month sooner than those sown in spring, an important object in a moist climate.

5138. The quantity of seed, where oats are sown broad-cast, is usually from four to six bushels to the acre. Land sown with potato oats requires less seed, in point of measure, than when any of the other sorts is used: first, because this variety tillers better than any other, and next, because having no awn, a greater number of grains are contained in a bushel.

5139. The mode of sowing oats is almost universally broad-cast; but where they are sown after turnips, or on other well pulverised soils, some adopt the row culture.

5140. The after-culture depends on the mode of sowing, but seldom consists of more than weeding before the flower-stalks begin to shoot up.

5141. In harvesting oats in England, they are generally cut down with the scythe, and carried loose to the barn or stack, but in the northern districts, and where threshing machines are used, whether sown, or what is most usual, reaped with the sickle, they are tied in sheaves to facilitate the process of threshing. Oats are ready for the scythe or sickle when the grain becomes hard, and the straw yellowish. They should generally be cut before they are dead ripe, to prevent the shedding of the grain, and to increase the value of the straw as fodder. They rarely get much damage when under the harvest process, except from high winds, or from shedding, when opened out after being thoroughly wetted. The early varieties are much more liable to these losses than the late ones; because the grain parts more easily from the straw,—an evil to which the best of grain is at all times subject. Early oats, however, may be cut a little before

which, to a certain extent, because the danger to which they are exposed from being plied; and if the sheaves are made small, the danger from shodding after being in temperature, because they are then easier ready for the stack. Under waxy management, however, a greater quantity of early oats will be lost during the harvest process than of the late ones; because the latter adhere firmly to the straw, and consequently do not drop so easily as the former (*Strens*.) In harvesting oats in wet seasons, the practice of galling the sheaves (5176.) is generally adopted. In Sweden, in most seasons, the oat crop is dried on frames or piles (704.) and in Russia, not only oats, but barley and rye, are kiln-dried in the straw.

5142. Kiln-drying oats and other cereals in the straw has been found necessary and is very generally practised through the north of Russia, Livonia, Courland, and Lithuania, being the last operation of harvest for preserving all kinds of corn, peas, beans, and buck-wheat. They are dried in the fields as much as can be, but, when brought home, they are kiln-dried, and are then ready to be either thrashed out immediately or put up in lutes, without any danger of either corn or straw becoming musty or rotting. The common practice of the house is, during winter, to thrash out by degrees, as in this country their oats and barley in order to have straw fresh for their cattle, such straw being their only provender. The process of kiln-drying by no means prevents the germination of the grain when used for seed, while it not only preserves the grain and straw but improves their taste and salubrity. It enables Russia to export large quantities of rye and wheat, with less risk of damage to the grain than is incurred by other nations of the north of Europe.

5143. The kiln (*Fig 728*.) is in general and established use throughout Russia, for the purpose of drying corn in the straw is heated commonly by fire of wood. It is a simple and cheaply erected structure, the walls eight feet high, and fifteen feet square within. At this height there are two strong cross-beams (a), to support the small timbers, laid over them as ribs. The corn stands in sheaves above these ribs (b), closely set up, the head ends of the sheaves down, the kiln being closed by a simple ceiling of cross joists at this height, covered with turf.

Any cheap and ordinary roof answers to cover the whole. The fire-place is constructed so as to throw back the ascending spark a small porch (c) directly opposite to the fire-place, prevents violent blasts of wind, and covers from rain the fuel and the attendant. About 500 sheaves (twenty-five shocks) of corn are dried at one time. It is put on in the evening, and left on the kiln through the night, after the wood has been burned into char coal, and the door above the fire-place closed. At one end of the kiln there is frequently an open shed or lair (d), for convenience in bringing corn to, or taking it from, the kiln.

5144. The produce of oats is generally considered greater and of better quality in the northern than in the southern counties, and the reasons are obviously that, in the former more attention is paid to their culture, and the climate is more favourable for the maturation of the grain. Ten quarters an acre is reckoned a good crop in the north, but the produce is often twelve and thirteen quarters, and the straw from two to three and a half loads per acre.

5145. The produce of oats in meal amounts to 6 lbs. for 14 lbs. of corn. Sir H. Davy found 100 parts of oats afford 59 parts of starch, six of gluten, and two of saccharine matter.

5146. The use of oats in the north, in Ireland, and in some parts of Yorkshire and Derbyshire, is partly for meal and partly for horse-food. In the south it is almost entirely for horse-food, poultry, and grows for gruel. It is occasionally malted and used in distillation. The fine powder which is produced by husking the corn, or making grit, forms the sowens of the Scotch (the summery of the Irish), an agreeable light and wholesome supper dish.

5147. The diseases of the oat are few. Sometimes it is found attacked by the smut; but the more common injury sustained by oats is from wire-worms, or larvae of insects which generally abound in lands newly broken-up from turf. One of the most certain modes of avoiding these is, by not ploughing the ground, especially if old turf, till immediately before sowing. By this means the insect is turned down, and before it can work its way to the surface (if ever it does) the corn is beyond its reach. In this way gardeners destroy and retard the progress of the gooseberry caterpillar by digging under the bushes; for it is found that the eggs and larvae of insects, like weeds and bulbs, when buried too deep in the ground, have their progress retarded, or their vital principles destroyed. In late harvests, more especially in the northern parts of the island, the oat is liable to be frosted and rendered unfit for seed before being harvested. There is no remedy for such an accident; but we have shown (4907) how it may be detected, so as not to disappoint the sower of such grain. (*Encyc. of Gard.* 4063.)

Section V. Cereal Grasses cultivated in Europe, some of which might be tried in Britain.

5148. The cereal grasses which the climate of Britain does not readily admit of cultivating, are the wheat, Canary corn, millet, and rice.

**Synonym 1** *Maize*, or *Indian Corn*. — *Zea Mays* L.; *Monarda Trifurcata* L., and *Crucifera* F. *Le Maïs*, or *Mil de Turquie*, Fr.; *der Mais*, Germ.; *Grain sacro*, Ital.; and *Mais*, Span.

5149. *The maize* is the noblest looking of the cereal grasses. It is considered to be a native of South America, to have been cultivated in Mexico and Peru from time immemorial, to have been introduced to Europe about the beginning of the 16th century, and to England in 1562. It is at present cultivated in almost every part of the universe where the summer temperature equals or exceeds that common to latitude 45°, and even to 48°. In France, in Arthur Young's time (1787), the principal country of the maize was to the south of a line drawn from Bordeaux to Strasbourg, in lat. 48° 35' but it is at present cultivated as far north as Nancy, which is in latitude 49° — a fact which shows that this grain is taking a wider range of temperature. "It flourishes on the western continent from about the 40th degree of southern to higher than the 45th degree of northern latitude. It is extensively produced in Africa and in Asia on all the shores of the Mediterranean, in Spain, Italy, part of France, and the countries of the Levant, it is the food in most common use. Of the cultivated *Cerealia*, indeed, it is that which, next to the rice, supplies food to the greatest number of the human race and it may be held to be the most valuable gift of the new world to the old." (*Quar. Jour. Ag.* v. 435.) In England it has been cultivated for upwards of a century, in nursery gardens in the neighbourhood of the metropolis, for the curious purpose of supplying seedmen in all parts of the island with ears of the corn to ornament their shop windows: it has also been grown in the kitchen gardens of some individuals who have lived in America, for the purpose of using the ears in a green state. It has been tried also in the fields, and more especially in 1828 and 1829, in consequence of the public attention being called to the subject by Mr. Cobbett.

5150. As a *bread corn* it cannot be greatly commended. The ear is highly productive of *flour* but that flour is deficient in gluten, and cannot be made into bread without a large admixture of the flour of wheat. For fattening cattle and poultry of every description it is found excellent, and its culture in Europe can only be recommended with a view to this object.

5151. *Varieties*. Like other plants which have been long in cultivation in various countries, there are

739

numerous varieties of the maize. According to La. gree, there are 150 varieties known in Spain. That grown in the warmer parts of America is called the large yellow *Maïs jaune, grand*, Fr. (*Ag.* 739.) There is a large red, which differs from the other only in the colour of the skin of the grain both have very large and handsome ears (*Ag.* 739.) There is the large yellow flint, the large white flint, the sweet corn, the pearl corn, the maize quarantina, ripening in sixty days, and the Egyptian or chicken corn. *Maïs à poulet*, le plus petit et le plus précoc, of Villamain's catalogue. There is also what is called Cobbett's corn (*Ag.* 731.), which seems to be nothing more than the *Maïs quarantina*. The two last varieties have small handsome ears (*Ag.* 731. and 732.), and can hardly be distinguished from each other. All these sorts have been tried together in the same field, and the Egyptian or chicken corn found decidedly the most early and the *Maïs quarantina*, forty days corn, or Cobbett's corn, next. These two sorts, therefore, alone deserve culture in this country. The *Zea Cuvensis*, the *Valparaiso* corn, is a distinct species, to which a sort of religious reputation is attached, on account of the grains, when roasted, splitting regularly into the form of a cross.

750

214. *Spelt and oblong.* A *Hot heavy soil*, which will grow good wheat, tobacco, or potatoes, will

grow the strongest plants; but the ears on such plants will be much less likely to ripen than that produced on a dry, sandy, or calcareous soil. It must be obvious, from what has been before advanced, that there are few if any parts of Britain north of York where the climate will be at all suitable to this grain.

513. *Culture.* This grain is almost everywhere sown or planted in rows, placed at such a width as to admit of horse-hoeing the intervals. When this is practised, as the grain contains very little gluten, the crop may be considered as a good preparation for wheat in very rich soils. It accordingly precedes that grain in the best cultivated parts of North America, but we question if it would be advisable to follow this practice in old cultivated countries, notwithstanding that maize and wheat differ so much in regard to gluten.

514. *The preparation of the soil may be the same as for a crop of barley, according to Cobbett, but we should say, the same as for a crop of turneps on the raised ridges or Northumberland system.*

515. *Sowing.* The quantity of seed required is from one bushel to three bushels per acre. In Long Island, near New York, the time of sowing is from the 15th to the 30th of May, in France, from the 15th of April to the 15th of May; in England, from the 15th of April to the 30th of the same month, according to Cobbett, but we have no doubt that, in situations where the earliest varieties will succeed at all, they will succeed if sown a week or ten days later. The grain will retain its vegetative powers for at least six years. (*Gard. Mag.* vol. vi. p. 246.)

516. *The mode of planting the ears in America is by drawing shallow drills, commonly three or four feet distant from each other, and dropping the seeds by hand, at eight inches apart, in the row.* This distance is evidently too great for the early French varieties, and we think three furrows, or twenty-seven inches, the necessary width between rows of potatoes and turnips, much more suitable. We should decidedly prefer dibbling, either by hand or by a machine, to opening a drill and depositing the seeds. In several places in France the seeds are sown broadcast and harrowed in, and the after-culture consists in hand-hoeing between them. By sowing on raised drills the horse-hoeing system may be applied as effectually as in the culture of turnips or beets. Cobbett recommends intervals between the rows of five feet, and the plants at six inches' distance in the row, with a view to admit a superior degree of tillage between, with a view to the wheat crop. He also describes the mode of planting in hills. The situations of these hills having been marked out by a light plough, or even by trailing a log of wood, first in one direction and then in the opposite direction at right angles to the former, so as to leave the furrows in squares, the planter takes a hoe, and at every intersection of the lines makes a little hole about an inch and a half deep, and about six inches in diameter, and in this hole five or six seeds are regularly distributed, and covered over with fine earth to the depth of an inch and a half. It is evident that by this mode of planting the ground may be very thoroughly worked during the growth of the crop, but it is evident also that it could only be adapted to this country on dry soils, that would admit of being kept during spring and autumn without water furrows.

517. *Transplanting* maize may be adopted on a small scale, the advantages of which are that the ground may be better prepared before planting, and that the crop may be made to come in in succession with one which has stood in the ground during winter. The plants may be raised in a bed, and protected by straw, or they may be raised in a warm border of dry rich soil, covered with straw or sawdust raised up to the common soil, the mulberry, or the walnut are in leaf; they may then be carefully raised and transplanted to the field, with a small portion of earth attached to each, planted with a spade or trowel, and watered unless it should happen to rain.

518. *The after-culture, according to Cobbett, commences with covering away birds and destroying slugs, and afterwards in weeding weeds and stirring the soil.* The plants will be one foot and a half high in July, and no one at that season, Cobbett says, need be afraid of tearing about the roots with the plough as much as he will. One thing is certain, he says, that if the ground between the rows be not ploughed at all, there will be no crop at all. The last plough with the plough is earthing up, which is said to be useful for two purposes: first, to keep the plants steady in case of very rough winds; and, second, to give it a fresh plant of roots. "Leave a corn-plant with neither but first hoeing, and without earthing up, and you will see all around its base coming out just above the ground, and going immediately down into the ground."

519. *Thinning the plants.* The male and female blossoms being on different parts of the plant, have given rise to this operation. The male flowers are always situated on the top or summit of the stem, and the female flowers lower, near the bottom. The flowers at the top having performed their function, descend the pollen on the stigma beneath, become no longer necessary to the plant; and they, accordingly, with all the elevated part of the stem which supports them, may be wholly removed. The process is termed topping by the Americans, and is adapted with the blades or leaves may be also stripped v

**516th Injury.** The period for performing this is dictated by the state of firmness of the vegetation. "The time for cutting is, when you, upon touching the husk, upon a little of the top of the ear, find the grain of the corn to be hard,--not hard enough to grind, nor dry--but hard enough to resist the strong pressure of the thumb nail. A second criterion is, all the husks having completely gained the seed, and the husk being completely dead and dry. A third is, the perfect darkness of the ends of the silk, where, instead of the bright green that appeared before, hanging gracefully down, like the beard of an extra ordinarily clean and fine-looking corn, you will perceive it to be a little cottony and of a whitish, or, at best, brown-looking tinge. When all these signs appear the top and the blades have performed their office, and the sooner they are taken away the better, because, after this, they do no good, and only serve to retard the ripening of the ears by the exclusion which they cause to the sun and the wind. The tops and leaves being removed, they are laid in bundles in the intervals, suffered to dry, and then carried away and stacked. The part of the produce, we are told, is now a precious deposit for fine water. It is liable to so inconvenient a which hay is not liable and weight for weight, and weather for weather, on acre of corn tops and blades will give more nutriment to cattle. They are reserved by the American farmers as food for their horses and oxen in spring, they are given to race horses and other delicate and highly prized animals. They are cut into chaff, and then mixed with barley and rye. Mr Cobbett has stated this part of the produce to be more valuable than a crop of hay, but he has not given us data, either as regards the weight of the crop, or the quantity of the animal it will feed, to enable us to judge of the correctness of his opinion. In France and southern Europe, these parts of the plant are, in like manner, used for fodder, but we are not aware that they are held in any thing like such high estimation as a crop of hay is with us." (*Treatise on Cobbett's Corn, and Quar Journ. Agr. vol. 1. p. 502.*)

**517th Harvesting.** The season of harvesting is generally October and November. In America, the ears are clipped or broken from the stem by the hand, and are carried directly to the barn floor to undergo the process of husking. The huskers, who are generally women and children, are seated around or alongside of a large heap of ears; they have baskets placed before them, they strip off the husks, fling them behind them, and throw the ears into a basket. These baskets as filled, are carried to the granary or corn-crib, as it is called in America. It may be two feet wide at the bottom, five feet high up the sides to the eaves, and five feet across at the top. It is open at the bottom, with wire at the sides, has a weather tight roof, and is raised from the ground by posts surrounded with tin as a protection against rats and mice. The husks form an excellent material for stuffing mattresses, and are used for this purpose in America and on the continent of Europe. The now almost useless stalks which remain in the fields in America are frequently burnt, but on the continent are used as litter for cattle running loose in the farmyard. The ears remain in the granary till they are wanted for feeding, or separating the grains from the receptacle. On the continent the ears are cut or broken from the stems as in America, and on a large scale are preserved in small open granaries, such as have been described, but more frequently they are hung up unhusked under the projecting eaves of all manner of buildings, and remain there till wanted for husking and shelling.

**518th Shelling or threshing.** This Cobbett tells us, is done in America by scraping the ears upon a piece of iron, fixed across a lat, into which the grains fall. The iron is commonly a bayonet. In this country there are machines of different kinds (*fig 754 and 7560*), which perform the operation of shelling with great rapidity, but whenever has a threshing machine might, by setting the rollers and drums somewhat wider than usual dispense with manual labour both in the operations of husking and shelling, and indeed we see no reason why the crop should not be harvested like a crop of drilled beards, with Gladstone's beam reaper (*5740*) and sheaved, shocked, stacked, and threshed, like any other grain.

**519th Produce.** In America and Australia, the produce in corn is from fifty to seventy bushels to the acre on the continent it is generally between fifty and sixty, and the produce in this country as it appears by some experiments recorded in the *Genl. Mag. vol. vi. p. 60 to 67* would probably be similar, notwithstanding the circumstance of Mr Cobbett, Mr Moore of Stately in Bedfordshire, and some others, having raised on small spots at the rate of 100 bushels per acre and upwards. The produce in straw in America and warm countries where the tallest sorts can be grown, is considerable, but in this country where only the dwarfest sorts could be cultivated with success, it would not equal that of a crop of oats or barley.

**520th.** The application of this crop, according to Cobbett, is various and important--"rag-feeding sheep-feeding, oxen and cow feeding, poultry feeding, horse-feeding and man-feeding to which we may add fish carp being fed with maize in France. For man-feeding" it is only made use of in America till the farmer can afford to grow wheat, and on the continent it is only used as a bread corn by the poorest of the people. The wretched inhabitants of the southern part of the Neapolitan territory live chiefly on maize, as those of some mountainous districts in the north of Italy live on bread made from chestnuts, or buck-wheat. The most important purpose to which the corn uncultured can be applied in Europe, appears to us to be the feeding of poultry. All the fat geese noted for their large livers in the north west of France and south-east of Germany are fed with maize, the grains unbroken, and the smaller poultry in these countries are also chiefly fed with this corn, broken or ground into meal.

**521st Turkey feeding.** According to Cobbett, is one of the most purposes to which the corn may be applied in this country. "In W. Hildes, last spring, one single peck, out of a large sack, out of which we took time for weighing three quarters of a peck. We followed corn, and fed thirty turkeys in the same manner, and so to grow and fatten, which he still makes this either of the turkey. They will not fat in this manner in a short space of time. If you wish to have fresh eggs in winter, you must resort to no stopping of laying in heat or in winter, as the geese have been used of the feed of maize, as the French do; but to make such a feed about laying the hens warm give them plenty of corn whole and you will have fresh eggs all the winter long. In the very little children, or very young children, you must give maize in a crushed state, but they may soon take it down whole; and, large as is, the geese will eat it that is fed on the farm, and if you be much forward with them, and do not wish to have numerous and early hatched of their ears getting, you must feed the poultry in the corn, as stated by them during the month of March, however, it is considerably short; for the grain is so large that their crops are filled in a minute. It is very well known that,

in order to have fat turkeys, or even, really fat swine, we are compelled to resort to crumming. If the farmer's wife have a dozen of these, then she sits off the corn twice weekly also to do so, with her husband upon her back, or rather upon her left side, with her head, pulled over an oblong frame, and with a bowl of warm milk, or with some green water, taking one turkey out of the crop at a time upon her left, forcing its mouth open with her left hand, putting in the milk with her right, and stroking with her fingers the outside of the back, so that she can descend into the crop, and every now and then covering the opening of the warm liquid, upon the principle that good, warm, downy food drink. There she sits, if she has two dozen of these animals to crum, for some time, and when she finishes they repeat the feed and finish their meal, and repeat the process with the contents of the bowl. It is a pleasant, agreeable, time-consuming, and useful job; it takes up a great deal of time; and yet these things which we made particularly the without this operation. In which case, in 1800, some of the very most, light, and strong, and of the most elegant in the country of North and South, of all these women could be brought together, and come to half and day

and sometimes in this country; and the great or Indian millet (*Ehlers*), cultivated in India, Italy, and America.

5174. Of the common millet there are three species: *Setaria germanica* (fig. 736 a), a native of the south of Europe; the *S. italica* (b), a native of the East Indies; and the *Setaria italica* (c) also of Indian origin.

736

5175. The German millet (*Setaria germanica*, Fr.; *S. germanica*, c) rises with a jointed reed-like stalk, about three feet high, and about the size of the common reed, with a leaf at each joint a foot and a half long, and about an inch broad at the base where broadest, ending in an acute point, rough to the touch embracing the stalk at the base, and turning downwards about half the length. The stalks are terminated by compact spikes, about the thickness of a man's finger at bottom, growing taper towards the top, eight or nine inches long, and closely set with small roundish grain. It is annual, and perishes soon after the seeds are ripe. There are three varieties of it, the yellow, white, and purple grained. It was formerly cultivated for bread in some of the northern countries.

the top of the sheath, which embraces and covers that joint of the stalk below the leaf, and is clothed with soft hairs; the leaf has none but has several small longitudinal furrows running parallel to the midrib. The stalk is terminated by a large loose panicle hanging on one side. Of this species there are two varieties, the brown and the yellow; the latter of which was formerly in cultivation, and is now sometimes sown for feeding poultry and as a substitute for rice.

737

5176. The Italian millet (*Pennisetum glaucum*, L.; *Millet à grappe*, Fr.; *Setaria italica*, c) rises with a reed-like stalk, nearly four feet high, and much thicker than that of the preceding; the leaves are also broader. The spikes are a foot long, and twice the thickness of those of the common millet, but not so compact, being composed of several roundish clustered spikes; the grain is also larger. There are two or three varieties of this differing only in the colour of the grain. It is frequently cultivated in Italy (whence its trivial name), and other warm countries. It is a native of both India, and of Cochin China.

5177. The Polish millet, or manna grass of the Germans (*Digitaria sanguinalis* formerly *Panicum sanguinalis*, fig. 737) is a low decumbent, annual plant, seldom rising above nine inches or a foot high, with hairy leaves and slender panicles. It tillers much, and forms a close tuft, spreading and rooting at the joints. It is a native of England but not common. It grows in abundance in Poland and is sometimes cultivated, the seeds being used like those of the other millets as a substitute for rice or sago.

738

5180. The great or Indian millet (*Ehlers* *Sorghum L. Sorghum vulgare*, W. ex. fig. 739. *Sorgho, gros millet d'Italie*, Fr.; *Sorghosum*, Ger. *Sorgho*, Ital. and *Melao*, Span.) has a stem which rises five or six feet high, is strong reedy and like those of the maize, but smaller. The leaves are long and broad, having a deep furrow through the centre, where the midrib is depressed in the upper surface, and is very prominent below. The leaves are two feet and a half long, and two inches broad in the middle embracing the stalks with their base. The flowers come out in large panicles at the top of the stalks, resembling, at first appearance, the male spikes of the Turkey wheat: these are succeeded by large roundish seeds, which are wrapped round with the chaff. This grain is a native of India, where it is much used to feed poultry and is frequently sent to Europe for the same purpose. It is much cultivated in Arabia, and most parts of Asia Minor, and has been introduced into Italy, Spain, Switzerland, and some parts of Germany, also into China, Cochin China, and the West Indies, where it grows commonly five or six feet high or more, and being esteemed a hearty food for labourers, is called negro Guinea corn. Its long awns or bristles defend it from the birds. In England the autumn is seldom dry and warm enough to ripen the seed well in the field. In Arabia it is called dove or dove; the flour is very white, and they make good bread of it, or rather cakes, about two inches in thickness. The bread which they make of it is some parts of Italy is dark and coarse. In Tuscany it is used chiefly for feeding poultry and pigeons, sometimes for swine, kine, and horses. Camperius says, that nettles fed on the green herb are apt to swell and die, but thrive on it when dried. They make brushes and brooms of its stalks in Italy which Ray observed in the shops at Venice, and which are sent to this country. Of this species there are two distinct varieties; one distinguished by black, and the other by red, husked seeds, besides subvarieties.

5181. The only sorts of millet which can be cultivated with success in this country are the German, cultivated, and the Polish sorts. According to Professor Thaur, the cultivated is to be preferred, as having the largest grain.

5182. The soil for the millet should be warm, sandy, rich, and well pulverised to a good depth. The seed is sown in May, very thin, and not deeply covered. In the course of its growth no plant, Professor Thaur observes, is more improved by stirring the soil, after which it grows astonishingly fast, and smothered all weeds.

5183. In harvesting the millet, great care is requisite not to shed the seed, and, as it ripens rather unequally, it would be an advantage to cut off the spikes as they ripen, as

in making fuel. No grain is easier to thresh, or to free from its husk by the mill. It is used instead of rice, and in Germany bears about the same price. It produces a great bulk of straw, which is much esteemed as fodder.

5164. The great Indian millet will grow in this country to the height of five or six feet; but will not ripen its seed, or even flower, if the season is not dry and warm. If its culture is attempted, it should be raised in a hotbed and transplanted.

#### SUMMARY. 4. Rice, and some other Cereæ Græminæ.

5165. The rice (*Oryza sativa*, Ag. 739.) has been tried in this country, and, if sown very early, would probably ripen its seeds. The hill variety which does not require watering, would probably succeed best. But there is no inducement to cultivate this and other grains or seeds when they can be imported at so low a rate. We merely introduce them to record the resources of British agriculture in case of necessity.

5166. The *Zizania aquatica* (Ag. 740.) might be cultivated on the margin of ponds for its seeds, which much resemble those of Polish millet.

It is exceedingly prolific, grows in great luxuriance, and produces abundance of bladed staminate seeds, in all the shallow streams of the dreary wilderness in north-west America, between the Canadian lakes and the hilly range which divides Canada from the country on the Northern Pacific Ocean. Its seeds contribute essentially to the support of the wandering tribes of Indians, and feed immense flocks of wild swans, geese, and other water fowl, which resort there for the purpose of breeding. Productive as is this excellent plant, and habituated to an ungenial climate, and to situations which refuse all culture, it is

surprising, says Pinkerton (Geog. vol. iii. p. 330.) that the European settlers in the more northern parts of America have as yet taken no pains to cultivate and improve a vegetable production which seems intended by nature to become, at some future period, the bread corn of the north.

5167. The *Glycine fistula* resembles the *Zizania*, and the seeds are used in Germany like those of Polish millet. Various species of *Panicum*, *Hordeum*, and *Bromus* afford tolerable supplies of edible seeds.

5168. The buck-wheat (*Polygonum Fagopyrum*; *Ris*, Fr., *Reis*, Ger., *Riso*, Ital.; *Arroz*, Span.) is vulgarly considered as a grain but not being a bread-corn grass, we have classed it among manufacturing plants. (Chap. VIII. Sect. IV.)

### CHAP. III.

#### Culture of Leguminous Field-Plants, the Seeds of which are used as Food for Man or Cattle.

5169. The seeds of the cultivated legumes are considered to be the most nutritious of vegetable substances grown in temperate climates. They contain a large proportion of matter analogous to animal substances, having when dry the appearance of glue, and being as nourishing as gluten. To the healthy workman this substance supplies the place of animal food, and Von Thier states, that in Germany neither sailors nor land labourers are content unless they receive a meal of legumes at least twice a week. The straw or husks, he says, cut before it is dead ripe, is more nourishing than that of any of the cereal grains. But leguminous plants are not only more than all others nourishing to man and animals, but even to vegetables they may be said to supply food; since they are not only known to be less exhausting to the soil than most other plants, but some of them, and more especially the lupine, have been ploughed in green as manure from the earliest times. Many scientific agriculturists consider a luxuriant crop of peas or tares as nourishing the soil by stagnating carbonic acid gas on its surface which corresponds with the universal opinion of their being equal to a fallow, and with the value set on them in rotation, as already explained. (1292.) Two seasons may be given for the circumstance of peas and tares not exhausting the land so much as other crops first, because they form a complete shade for the ground; and next, because they drop so many of the

leaves upon the surface. The legumes cultivated in British farming are, the pea, bean, turn, and vetch, to which might be added the lentil, kidneybean, and chick pea.

5190. The nutritive products of these plants are thus given by Sir H. Davy, Ekinhoff, and Thier —

Scut. I. The Pea. — *Pisum sativum* L. *Diadelphus Decandrus* L. and *Leguminosae* J. Les Pois, Fr. Erbsen, Ger. Pisello, Ital. and Peasles, Span. (fig. 741)

741

5191. The pea is the most esteemed legume in field cultivation, both for its seed and haulm. It is supposed to be a native of the south of Europe, and was cultivated by the Greeks and Romans. In this country it has been grown from time immemorial but its culture appears to have diminished since the more general introduction of herbage, plants, and roots and the pea, except near large towns for gathering green, and in a few places for boiling has given way to the bean or to a mixture of peas and beans. There are various inducements, however to the cultivation of peas in dry warm soils near large towns. When the crop is good and gathered green, few pay better the payment is always in cash, and comes into the pocket of the farmer in time to meet the exigencies of the hay, and sometimes even of the corn, harvest. The ground, after the peas have been removed, is readily prepared for turnips which also pay well as a retail crop near towns, and the haulm is good fodder.

5192. The varieties of the pea are numerous but they may be divided into two classes those grown for the ripened seed, and those grown for gathering in a green state. The culture of the latter is chiefly near large towns, and may be considered as in part belonging to gardening rather than agriculture. There has lately a new sort of pea been brought into notice about Banbury in Oxfordshire. It is called the "nimble hog pea." It appears to be a grey variety of the early frame, as it has single flowers, and is fit to cut about the end of June notwithstanding it must not be sown earlier than the middle of April. On the excellent land about Banbury the produce is four quarters to the acre, and turnips sowed on the stubble are up and sometimes hoed out before the regular turnip crop!

5193. The grey varieties (*Polygona* *Poa-nigra*, *Marble* Fr.) are, the early grey the late grey and the purple grey to which some add the Marlborough grey, and hura grey.

5194. The white varieties (*Poa alba* Fr.) grown in fields are the pearl, early Charlton golden lotspur the common white or Suffolk, and other Suffolk varieties.

5195. New varieties of the pea are readily procured by selection or impregnation of which a striking example given by Knight has been already referred to. (632.)

5196. In the choice of sorts, where it is desired to grow grey peas for the sake of the seeds or corn, the early variety is to be preferred in late situations, and the late variety in early ones; but when it is intended to grow them chiefly for covering the ground and for the haulm, then the late varieties claim the preference, and especially the purple grey. Of white peas, to be grown for gathering green, the Charlton is the earliest, and the pearl or common Suffolk the most prolific. When white peas are grown for boilers, that is for splitting, the pearl and Suffolk are also the best sorts.

5197. To leave resources to early sorts is supposed by some to be of considerable importance in the economy of a farm, where the nature of the soil is suitable, as by such means the crops may in many cases be cut and secured while there is leisure, before the commencement of the wheat harvest and that where the nature of the soil is dry and warm, and the pea crop of a sufficiently forward kind, it may be easy to obtain a crop of turnips from the same land in the same year, as has been suggested above. But in this view it is the best practice to put in the crops in the new method, and keep them perfectly clean by means of selective hand and have hoeing as in that way the land will be in such a state of preparation for the turnips as only to require a slight ploughing, which may be done as fast as the pea crop is removed, and the turnips may be drilled in as quickly as possible upon the newly turned up earth. In some particular districts such a third crop is even put into the same land, the turnips being sold off in the autumn, and afterwards cultivated for the purpose of grass in the following spring. This, according to Maitland, is the practice in

some places in Midland. But it is obviously a method of cultivation that can only be attempted on the warm and fertile kinds of turnip soil, and where the pea crops are early; on the cold heavy and wet descriptions of soil it is obviously impracticable, and wholly improper.

§198. The soil best suited for peas is a dry calcareous sand; it should be in good tilth, not too rich nor dumped along with the crop. In Norfolk and Suffolk peas are often sown on clover leys after one furrow, or after corn crops on two furrows, one given in autumn, and the other early in spring.

§199. The climate required by the pea is dry and not over warm, for which reason, as the seasons in this country are very often moist and sometimes exceedingly dry and hot in June and July the pea is one of the most uncertain of field crops.

§200. The season of sowing must differ considerably according to the intentions of the cultivator.

§201. For peeding early to be sold green, they should be sown at different times, from January to the end of March, beginning with the driest and most reduced sorts of land, and with this intention in some southern counties they are sown in the autumn. For the general crops from February to April, as soon as the lands can be brought into proper order, is the proper season; the grey sorts being sown in the early spring, and the white sorts in the late. Young says, that where these crops cannot be sown in February, they should always be completed in the following month. It is observed by the same writer that, in sowing after a single furrow the white bottling pea, of many sorts and under various names, is more tender than the greys and various kinds of hog peas; but he has many times put them late the ground in February and, though very smart frosts followed, they received no injury. He has uniformly found, that the earlier they were sown the better. There is also a particular motive for being as early as possible, that is, to get them off in time for turnips. This is most profitable husbandry and should never be neglected in dry and warm soils and situations. If they are sown in this month, and a right sort chosen, they will be off the land in June, so that turnips may follow at the common time of sowing that crop.

§202. Stamping the seed in water is sometimes practised in late sowings.

§203. The quantity of seed must be different in different cases and circumstances, and according to the time and manner in which the crop is put into the ground, but, in general, it may be from two and a half to three bushels, the early sowings having the largest proportion of seed. In planting every furrow slice, Young says, two bushels and a half constitute the usual proportion, but, when drilled at greater distances, six or seven pecks will answer.

§204. The most common mode of sowing peas is broad-cast, but the advantages of the row culture in the case of a crop so early committed to the soil must be obvious.

§205. The best farmers always sow peas in drills either after the plough, the seed being deposited immediately in every second or third furrow, or if the land is in a pulverized state, by drawing drills with a machine or by ridging. In Norfolk and Suffolk peas are generally drilled on the back of the furrow, sometimes one and sometimes two rows on each, but drilling in no manner appears to us so well suited for a farmer's purpose as the drill. In Kent, where immense quantities of peas are grown both for gathering green and for selling ripe to the customers, they are generally sown in rows from eighteen inches to three feet asunder according to the kind, and well cultivated between. Peas laid a foot below the surface will vegetate, but the most approved depth is six inches in light soil, and four inches in clay soil, for which reason they ought to be sown under furrow when the ploughing is delayed till spring. Of all grain beans excepted, they are the least in danger of being buried.

§206. The after culture given to peas is that of hoeing, either by hand or horse. Where the method of hand-culture prevails, it is the general custom to have recourse to two hoeings, the first when the plants are about two or three inches in height and again just before the period in which they come into blossom. In this way the vigorous vegetation of the young crop is secured, and a fresh supply of nourishment afforded for the setting of the pods and the filling of the peas. At the latter of these operations the rows should be laid down, and the earth well placed up to them, the weeds being previously extirpated by hand labour. It has been stated, that in some parts of Kent, where this sort of crop is much grown, it is the practice, when the distance of the rows will permit, to prevent the vegetation of weeds, and forward the growth of pea crops, by occasionally horse-hoeing, and the use of the brake-harrow, the mould being laid up to the roots of the plants at the last operation by fixing a piece of wood to the harrow. This should, however, only be laid up on one side, the peas being always placed up to that which is the most fully exposed to the effects of the sun.

§207. In harvesting the ripened peas considerable care is requisite, both on account of the seed and haulm.

§208. When pea crops become ripe they wither and turn brown in the haulm or straw and the pods begin to open. In this state they should be cut immediately, in order that the loss sustained by their shedding may be as little as possible. It is observed that in the late or general crops, after they are mowed or rather cut up by means of a hook, it is the usual practice to put them up into small heaps, several weeks, which are dressed by setting small parcels against each other, in order that they may be more perfectly dried both in the seed and straw, and be kept from being injured by the moisture of the ground. But, in the early crops, the haulm is hooked up into loose open heaps, which, as soon as they are perfectly dry are removed from the ground and put into stacks for the feeding of animals, which are said to thrive much so well on it as on hay. When intended for hay, the best method would seem to be that of hooking them up into small and stacked with their other seed. Young says, that forward white peas will be fit to cut early in July; if the crop is very great they must be hooked, but if small, or only middling, mowing will be sufficient. The seeds and haulm of peas being very succulent, they should be taken good care of in wet weather: the stalks, called straw or haulm, should be turned, or they will receive damage. When your stacks always be perfectly dry before they are housed, or they will sell but indifferently, as the haulm is much more of the grain are considered more in them than in hay peas at market. The green crop, if well cultivated, is very good fodder for all sorts of cattle and for sheep; but if it is covered with wet, or if the haulm are not turned, it can be used only to litter the farmyard with. It is the practice in some districts to remove the haulm, as soon as it has been cut up by hooks constructed

with sharp edges for the purpose, to every 5th ridge, or even into an adjoining green field, in order that it may be the better suited for use as cattle-food, and at the same time allow of the animal being immediately prepared for the succeeding crop. When wet weather happens whilst the peas lie in waste, it occasions a considerable loss, many of them being shed in the field, and of those that remain a great part will be so considerably injured as to render the sample of little value. This liability in peas to rust is a wet harvest, together with the great uncertainty throughout their growth, and the frequently inadequate return in proportion to the length of haulm, has discouraged many farmers from sowing so large a portion of this pulse as of other grain; though on light lands which are in tolerable heart, the profit, in a good year is far from inconsiderable.

5208. *In gathering green peas for the market* it is frequently a practice with the large cultivators of early green-pea crops in the neighbourhood of London to dispose of them, by the acre, to inferior persons, who procure the podders, but the smaller farmers, for the most part, provide this description of people themselves, who generally apply at the proper season.

5210. *The business of picking or podding the peas* is usually performed by the labourers at a fixed price for the sack of four bushels. The number of these labourers is generally in the proportion of about four to the acre, the labour proceeding on the Sundays as well as other days. It is sometimes the custom to pick the crop over twice, after which the rest are suffered to stand till they become ripe, for the purpose of seed. This, however, mostly arises from the want of pickers, as it is considered a loss, from the peas being less profitable in their ripe state than when green. Besides they are often improper for the purpose of seed, as being the worst part of the crop. It is therefore better to have them clear picked when hands can be procured. After this they are loaded into carts, and sent off at suitable times, according to the distance of the situation, so as to be delivered to the saleroom in the different markets from about three to five o'clock in the morning. In many cases in other parts, the early gatherers are, however, sent to the markets in half-bushel doses, and are frequently disposed of at the high price of five shillings the sack; but at the after periods they are usually conveyed in sacks of a narrow form, made for the purpose, which contain about three bushels each which in the more early parts of the season, often fetch twelve or fourteen shillings the sack, but afterwards mostly decline considerably in some seasons so much as scarcely to repay the expenses. This sort of crop affords the most profit in such pea seasons as are richened to be so, or under such circumstances the peas are most retarded in their maturation or ripening and of course the markets kept from being overabundantly supplied.

5211. *The threshing of peas* requires less labour than that of any other crop. Where the haulm is to be preserved entire it is best done by hand as the threshing machine is apt to reduce it to chaff. But where the fodder of peas is to be given immediately to horses on the spot, the breaking of it is no disadvantage.

5212. *The produce of the pea* in ripened seeds is supposed by some to be from three and a half to four quarters the acre others, however as Donaldson, imagine the average of any two crops together not more than about twelve bushels and that on the whole, if the value of the produce be merely attended to, it may be considered as a less profitable crop than most others. But as a means of ameliorating and improving the soil at the same time, it is esteemed of great value.

5213. *With respect to the produce in green peas* in the haulm, the average of the early crops in Middlesex is supposed to be from about twenty five to thirty sacks the acre, which selling at from eight to eighteen shillings the sack afford about eighteen pounds the acre. The author of *The Synopsis of Husbandry* however states the produce about Dorking, in the county of Kent, at about forty sacks the acre, though he says fifty have sometimes been gathered from that space of land.

5214. *The produce of peas in straw* is very uncertain depending so much on the sort and the season in general it is much more bulky than that of the cereal grasses but may be compressed into very little room.

5215. *The produce of peas in flour* is as 3 to 2 of the bulk in grain, and husked and split for soups as 4 to 2. A thousand parts of pea flour afforded 11. Dury 574 parts of nutritive or soluble matter; viz. 501 of mediocrity or vegetable animal matter 22 of sugar 35 of gluten, and 16 of extract or matter rendered insoluble during the operation.

5216. *The use of peas for soups, puddings, and other culinary purposes*, is well known.

5217. *In some places* porridge brose and bread are made of pea-flour and reckoned very wholesome and substantial. In Strirlingshire it is customary to give pea or bean baccuits to horses, as a refreshment, while in the yoke. The portion of peas not consumed as human food is mostly appropriated to the fattening of hogs and other domestic animals and, in particular instances, supplies the place of beans, as the provender of labouring horses but care should be taken, when used in this way that they are sufficiently dry as, when given in the green state, they are said to produce the gripes, and other bowel complaints, in those animals. Bannister after observing that the haulm is a very wholesome food for cattle of every kind, says, there is generally a considerable demand for peas of every denomination in the market, the use to which they may be applied being so many and so various. The boilers, or yellow peas, always go off briskly; and the hog-peas usually sell for 6d. or 1s. per quarter more than beans. For feeding swine the pea is much better adapted than the bean, it having been demonstrated by experience, that hogs fat more kindly when fed with this grain than with beans, and, what is not easy to be accounted for the flesh of swine which have been fed on peas, it is said, will swell in boiling, and be well tasted; whilst the flesh of the bean-fed hog will shrink in the pot, the fat will boil out, and the meat be less delicate in flavour. It has, therefore, now become a practice with those farmers who are curious in their pork, to feed their hogs on peas and barley-mead; and if they have no peas of their own growth they rather choose to be at the expense of buying them, than suffer their hogs to eat beans. Nay, so far, says he, do some of them carry their prejudice in this particular, as to reject the grey peas for this use, as bearing too near an affinity to the bean, and therefore reserve their growths of white peas solely for hog feeding.

5218. *In boiling* peas some examples, without reference to variety, all or moulder down slowly into pulp, while others continue to maintain their form. The former are called holters. This property of boiling depends on the soil; stiff land, or sandy land, that has been illed or marled, or to which gypsum has been applied, produces peas that will not melt in boiling, no matter what the variety may be. The same effect is produced on beans, on kidneybeans in the pod, and indeed on the seeds and pods of all leguminous plants; this quality having a great tendency to absorb gypsum from the soil. To counteract this effect in the boiling, it is only necessary to throw into the water a small quantity of subcarbonate of soda. (*Phil. de Bot. Agr. Feb. 1836.*)

5219. *Peas sown cut green and dried* is reckoned as nourishing as hay, and is considered excellent for sheep.

5220. In the rearing of any particular sort of peas for seed, they should be carefully looked over while in flower, in order to draw out all such plants as are not of the right kind; as there will always be, in every sort, some rough plants, which, if left to mix, will cause degeneration. As many rows as may be thought sufficient to furnish the desired quantity of seed should then be marked out, and left till their pods turn brown, and begin to split, when they should immediately be gathered up, with the haulm; and if the farmer has not room to stack them till winter, they may be thrashed out as soon as they are dry, and put up in sacks for use but particular care should be taken not to let them remain too long abroad after they are ripe; as wet would rot them, and heat, after a shower of rain, makes their pods burst in such a manner that the greater part of their seeds would be lost.

5221. The diseases of peas are few, and chiefly the worm in the pod and the fly on the leaves and flowers. They are also liable to be mowed or blighted. None of these evils, however, are very common; and there is no known way of preventing them but by judicious culture. Late sown peas are particularly liable to be injured by the mildew and Aphids and should either of these attack the plant before the pods are filled, they invariably fall. In 1836 almost all the crops of peas were destroyed by the Aphides, so that they were mown for the haulm only.

SECT. II. *The Bean.*—Vicia Faba L.; *Diastolipis Decandrie* L., and *Leguminosae J. Neeske*, Fr., *Bohm*, Ger., *Fava*, Ital. and *Aberjona*, Span.

5222. The bean is a valuable field plant, as affording food for live stock, and in part for man. It is said to be a native of Egypt; but, like other long domesticated plants, its origin is very uncertain. It has been cultivated in Europe and Asia time out of mind. Beans have been long known in Britain, but it is only of late years that they were extensively cultivated upon general soils, being formerly considered as adapted only to rich and moist clays. At that time they were all sown according to the broad-cast system, in which way, instead of benefiting the ground, they were of incalculable detriment. Weeds got away at the outset, and in dry seasons often ruined the crop whilst in every season the grass or perennial weeds which happened to be in the ground increased in strength and in quantity, the openness of the bean crop at bottom allowing them to thrive without interruption.

5223. The drilling of beans with a small mixture of peas is now become a general practice in every well cultivated district of the north, more particularly in those where soil and climate permit the practice to be successfully executed. In this way not only heavy crops are raised, but, what is of great importance, the ground is kept constantly in good order, provided suitable attention is bestowed upon the cleaning process. This is generally carried on by horse-hoeing the crop at different times, so long as the hoe can be used without doing damage and in this way an able auxiliary is brought forward to the assistance of summer fallow whereby less stress need be laid upon that radical process than otherwise would be indispensably necessary. (Brown.)

5224. The varieties of the bean may be included under two general heads, — the white or garden beans, and the grey or field beans.

5225. Of the white or garden beans (*Fava de marais*, Fr.) sown in the fields, the mazzagan and long-pod are almost the only sorts. Of the grey beans, that known as the horse bean, the small or ticks, and the poulton or Holghout, are the chief sorts. New varieties are procured in the same manner as in other plants. A variety is in use in some parts of Lincolnshire, called the winter bean (*Fève de l'hiver* Fr.). It is planted in October in the usual manner and is ready to harvest in the last week in July or the first week in August. They are said to have been introduced from the Continent in 1835. We have lately seen a field of this bean at the Oaks Farm, near Woking, in Surrey which was planted in October 1839, and in full bloom May 18th following. This circumstance, after so severe a winter is a proof to us that this is a most valuable variety. (*Gard. Mag.* vol. vi.)

5226. In the choice of sorts, tick beans are supposed by some farmers to be more productive than horse-beans, but the latter grow higher in the stem, and produce a more stagnated state of the air, or another the land more, consequently are the most suitable for the stronger sorts of soil and Young remarks, that "the common little horse-bean has the advantage of all others in being more generally marketable for in certain situations it is not always easy to dispose of ticks, Windsor, long-pods, and various other large sorts. They also grow higher, shade the ground in summer more from the sun, and yield a larger quantity of straw, which makes excellent manure. But some of the other sorts are generally supposed to yield larger products. In purchasing beans for seed, care should be taken to choose such as are hard and bright, without being shrivelled in their appearance."

5227. The best soils for beans are clays and strong loams. On such soils they generally succeed whins or oats, but sometimes also clover leys. Turp soils or sands are by no means proper for them.

5228. In the preparation of the soil much depends on the nature of the land and the state of the weather; for as beans must be sown early in the spring, it is sometimes impossible to give it all the labour which a careful farmer would wish to bestow. It must also be regulated in some measure by the manner of

sowing. To all extent it ought to be ploughed with a deep furrow after harvest or early in winter; and as two ploughings in spring are highly advantageous, the winter sowing may be given in the direction of the former ridges, in which way the land is easier dry in spring than if it had been ploughed across. The second ploughing is to be given across the ridge, as early in spring as the ground is sufficiently dry; and the third furrow either across the ridge or across the seed. (*Supp. 2d. Ed. 2d. ed. 1829*.)

5528. *Second sowing of the best bean-growers in Britain, gives the following directions:—* The furrow ought to be given early in winter, and as deep as possible, that the earth may be sufficiently loosened and room afforded for the roots of the plant to ascend for the requisite nourishment. This first furrow is usually given across the field, which is the best method when only one spring furrow is intended; but as it is now ascertained that two spring furrows are highly advantageous, perhaps the one in winter ought to be given in length, which lays the ground in a better situation for raising the ridges, and renders it easier dry in spring, than can be the case when ploughed across. On the supposition that three furrows are to be given, one in winter and two in spring, the following is the most eligible preparation.—The land being ploughed in length as early in winter as is practicable, and the cross gather and headland furrows sufficiently dug out, take the second furrow across the first as soon as the ground is dry enough in spring to undergo the operation; water-furrow it immediately, and dig again the cross gather and headland furrows, otherwise the benefit of the second furrow may be lost. This being done, leave the field for some days till it is sufficiently dry when a cast of the harrows becomes necessary so that the surface may be levelled; then enter with the plough and turn the drills. (*Treatise on Rural Affairs.*)

5529. *Manure is frequently applied to the bean crop, especially if it succeeds wheat.* By none, dung is spread on the stubble previously to the winter ploughing; but this cannot always be done in a satisfactory manner, at least in the northern parts of the island, unless during frost, when it may be long exposed to the weather before it can be turned down by the plough. The most desirable mode, therefore, is to lay the manure into drills immediately before the beans are sown. (*Supp. 2d.*)

5531. *The best sowing, according to Brown, is to apply the dung on the stubble before the winter furrow is given, which greatly facilitates the sowing process.* Used in this way a few stock must be used; but when the furrow is not so well provided, sowing dung becomes necessary though evidently of less advantage. At that season it may either be put into the drills before the seed is sown, or spread upon the surface and ploughed down, according to the nature of the drilling process which is meant to be adopted. Land dunged to beans, if duly hoed, is always of high order for carrying a crop of wheat in succession. Perhaps better wheat, both in respect of quantity and quality may be cultivated in this way than in any other mode of sowing.

5532. *The climate most favourable to the bean is one neither very dry nor very moist; the first brings on the fly, and the last prevents the setting of the blossoms.* In general, however a dry summer is most favourable to the production of seed, and moist weather to the growth of the haulm.

5533. *The time of sowing beans is as early as possible after the severity of winter is over; in the south, sometimes in January, but never later than the end of March, as the ripening of the crop and its safe harvesting would otherwise be very precarious in this climate.* Bannister thinks that the proper time for planting beans in Kent is towards the latter end of January or early in the following month though this business may be continued with advantage till the middle or latter end of March, if the weather should prevent their being got in at an earlier season but in general it is best to embrace the first opportunity of sowing them after Candlemas, as they often miscarry when the season is procrastinated beyond that time, especially if a dry summer should succeed.

5534. *The mode of sowing is almost always in rows.* Though still sown broadcast in several places, and sometimes dibbled, they are for the most part drilled by judicious cultivators, or deposited after the plough in every furrow or only in every second or third furrow. In the latter method the crop rises in rows, at regular intervals of nine, eighteen, or twenty-seven inches, and the hand-hoe ought invariably to be employed, but it is only where the widest interval is adopted that the horse-hoe can be used with much effect in their subsequent culture.

5535. *There are two modes of drilling beans.* In one of these the lands or ridges are divided by the plough into ridglets or one foot widths, at intervals of about twenty-seven inches. If dung is to be applied, the seed ought to be first deposited, as it is found inconvenient to run the drill-machine after wards. The dung may then be drawn out from the carts in small heaps, one row of heaps serving for three or five ridglets, and it is evenly spread and equally divided among them in a way that will be more minutely described when treating of the culture of turneps. The ridglets are next split out or reversed, either by means of the common plough or one with two mould-boards, by which means both the seed and the manure are perfectly covered. When beans are sown by the other method, in the bottom of a common furrow, the dung must be previously spread over the surface of the winter or spring ploughing. Three ploughs then start in succession, one immediately behind another and a drill harrow either follows the third plough or is attached to it, by which the beans are sown in every third furrow or at from twenty-four to twenty-seven inches asunder according to the breadth of the furrow.

5536. *Another approved way of sowing beans, when dung is applied at seed time, is to spread the dung and to plough it down with a strong furrow after this shallow furrow is drawn, into which the seed is deposited by the drill-machine.* Whichever of these modes of sowing is followed, the whole field must be carefully laid dry, by means of channels formed by the plough, and when necessary by the shovel; for neither then nor at any former period should water be allowed to stagnate on the land.

5537. *The dibbling of beans is considered by Arthur Young as an excellent method when well performed, but the great objection to it is the difficulty of getting it well done.*

5538. *When dibbling becomes the common husbandry of a district, the workmen find that great savings are to be made by it, and this is much too apt to make them careless and eager to earn still more; and if a very minute attention is not paid to them by the constant attendance of the farmer, they slide the holes so shallow that the first pack of a hawk's bill takes the seed and acres may be destroyed if the breed of these birds be encouraged.* Boys are employed six weeks together to keep the drills, but all works that depend on boys are horribly neglected, and thus the farmer suffers materially; however, if the seed is deposited two and a half or (better) three inches deep, it is not so easily spoiled. In some districts, as Middlesex, Surrey &c. the method is to plant this pulse in rows struck out by a line, by which a great saving is made in the article of seed, a circumstance which is thought to compensate for the extraordinary charge of this mode of husbandry; and thus far it may be fairly acknowledged that the method of planting beans by the dibber is greatly to be preferred to that of sowing the seed at random. The economy of this agricultural process is thus explained.—The rows are marked out one foot distant,

and the seed sown in three weeks before the first of May: the lines are stretched across the land, which are bound about the first week; no line is sown after the first of May, the seeds in which the line is stretched are sown by a single person, and the seeds are sown, and the seeds are sown, and the seeds are sown. The seeds are sown in three weeks before the first of May: the lines are stretched across the land, which are bound about the first week; no line is sown after the first of May, the seeds in which the line is stretched are sown by a single person, and the seeds are sown, and the seeds are sown. Great confidence must necessarily be reposed in the people who transact the business of planting beans for the winter; for if inclined to cheat, they have it in their power to deceive their employer, by throwing against part of the seed into the hedge; by which means their daily profits are considerably enhanced: their own better spirit, and every discovery effectually precludes all the apprehensions of the crop. Then, indeed, the frequent absence in the rows will give sufficient indications of the fraud; but by this time perhaps the villainous authors of the robbery may have escaped all possibility of detection, by having conveyed themselves from the scene of their iniquity.

5239. The quantity of seed allowed is very different in the southern and northern parts of Britain: in the former, even when the rows are narrow, only two bushels or two bushels and a half, but in Scotland, seldom less than four bushels to the English statute acre, even when sown in ridges twenty-seven inches distant, and a bushel more when sown broad-cast. When beans are sown or planted thick, the top pods only fill to the number of three, and four, and half a dozen when thin, the plants will pod and fill to the bottom. Both in the broad-cast and drill husbandry, it is common to mix a small quantity of peas along with beans. This mixture improves both the quantity and quality of the straw for fodder and the pea straw is useful for banding up the sheaves in harvest.

5240. The after culture of the bean crop commences with harrowing just before the young plants reach the surface. When sown in rows, in either of the modes already mentioned, the harrows are employed about ten or twelve days after, and, being driven across the ridges, the land is laid completely level for the subsequent operations, and the annual weeds destroyed.

5241. After the beans have made some growth, sooner or later according to the state of the soil with regard to weeds, the horse-hoe is employed in the intervals between the rows, and followed by the hand-hoe for the purpose of cutting down such weeds as the horse-hoe cannot reach; all the weeds that grow among the beans beyond the reach of either hoe, should be pulled up with the hand. The same operations are repeated as often as the condition of the land, in regard to cleanliness, may require.

5242. Before the introduction of the horse-hoe which merely stirs the soil, and cuts up the weeds, a common small plough, drawn by one horse, was used in working between the rows, and as still necessary where root-weeds abound. This plough goes one foot, or up and down in each interval, turning the earth from the beans, and forming a ridgelet in the middle: then hand-hoes are immediately employed; and, after some time, a second hand-hoeing succeeds, to destroy any fresh growth of weeds. The same plough, with an additional mould board, finally splits open the intermediate ridgelet and lays up the earth to the roots of the beans on each side. The benefit of laying up the earth in this manner, however, is alleged to be counterbalanced by the trouble which it occasions in harvest, when it is difficult to get the reapers to cut low enough, and it may be properly dispensed with unless the soil is very wet and level.

5243. In most cases, the grain is cut by hand, and it is exceedingly difficult to get the straw into a proper condition for the stack. In such cases, it has been found of advantage to switch off the succulent tops with an old scythe blade set in a wooden handle, with which one man can easily top-dress two acres a day. This operation it is said, will occasion the crop to be ready for reaping a fortnight earlier and also, perhaps, a week sooner ready for the stack-yard after being reaped.

5244. Before reaping beans the grain ought to be tolerably well ripened, otherwise the quality is impaired, whilst a long time is required to put the straw in such a condition as to be preserved in the stack. In an early harvest, or where the crop is not weighty, it is an easy matter to get beans sufficiently ripened but, in a late harvest, and in every one where the crop takes on a second growth, it is scarcely practicable to get them thoroughly ripened for the sickle. Under these circumstances, it is unnecessary to let beans stand uncut after the end of September or the first of October because any benefit that can be gained afterwards, is not to be compared with the disadvantages that accompany a late wheat seed-time.

5245. Beans are usually cut with the sickle, and tied in sheaves, either with straw ropes, or with ropes made from peas sown along with them. It is proper to let the sheaves lie untied several days, so that the winning process may be hastened, and, when tied, to set them up on end, in order that full benefit from the air may be obtained, and the grain kept off the ground. (Brown.)

5246. Beans are sometimes mown, and, in a few instances, even pulled up by the roots. They should in every case be cut as near the ground as possible, for the sake of the straw which is of considerable value as fodder and because the best pods are often placed on the stems near the roots. They are then left for a few days to wither and afterwards bound and set up in shocks to dry but without any head sheaves. (Supp. &c.)

5247. Beans are stacked either in the round or oblong manner, and it is always proper, in the northern counties at least, if the stack is large, to construct one funnel or more to allow a free circulation of air.

5248. The threshing of beans is nearly as easy as that of peas. Threshing them by a machine may be considered advantageous as breaking the coarser ends of the straw, and separating the earth from their root-ends, or roots, if they have been reaped by pulling.

5249. The produce of beans, when proper management is exercised, and where diseases have not occurred, is generally from twenty-five to thirty-five bushels per acre. Donalson says, that a crop of beans, taking the island at large, may be supposed to vary from sixteen to thirty bushels, but that a good average crop cannot be reckoned to exceed twenty. In Middlesex, Middleton tells us, that bean-crops vary from ten to eighty bushels per acre. They are rendered a very precarious crop by the ravages of myriads of small black insects of the *Aphis* kind. The lady-birds (*Coccinella*) are supposed to feed on them, as they are observed to be much among them. Foot note, the average produce is from

three and a half to four quarters per acre. In Kent, A. Young thinks they probably exceed four quarters; but in Suffolk, he should not estimate them at more than three; yet five or six are not uncommon.

5250. *The produce in Aconia*, in most seasons, is very bulky

5251. *In the application of beans*, the grain in Scotland is sometimes made into meal, the flour for bread, and the coarser for swine; but beans are for the most part applied to the purpose of feeding horses, hogs, and other domestic animals. In the county of Middlesex, all are given to horses, except what are preserved for seed, and such as are podded while green, and sent to the London markets. When pigs are fed with beans, it is observed that the meat becomes so hard as to make very ordinary pork, but good bacon. It is also supposed that the mealmen grind many horse-beans among wheat to be manufactured into bread.

5252. *The flour of beans is more nutritive than that of oats*, as it appears in the fattening of hogs; whence, according to the respective prices of these two articles, Dr Darwin suspects that peas and beans generally supply a cheaper provender for horses than oats, as well as for other domestic animals. But as the flour of peas and beans is more oily, he believes, than that of oats, it may in general be somewhat more difficult of digestion; hence, when a horse has taken a stomachful of peas and beans alone, he may be less active for an hour or two, as his strength will be more employed in the digestion of them than when he has taken a stomachful of oats. A German physician gave to two dogs, which had been kept a day fasting, a large quantity of fresh food, and then taking one of them into the fields, hunted him with great activity for three or four hours, and left the other by the fire. An emetic was then given to each of them, and the food of the sleeping dog was found perfectly digested, whilst that of the hunted one had undergone but little alteration. Hence it may be said, he found advisable to mix bran of wheat with the peas and beans, a food of less nutriment, but of easier digestion, or to let the horses eat before or after them the coarsest munitions of sour grass, which remain in moist pastures in the winter of lastly to mix finely our straw with them. It is observed in the fifth volume of *The Dutch Papers*, that it has been found by repeated experience, that beans are a much more hearty and profitable food for horses than oats. Being out of old oats the two last springs, the writer substituted horse-beans in their stead. In the room of a sack of oats with chaff, he ordered them a bushel of beans with chaff to serve the same time. It very soon appeared the beans were superior to the oats, from the life, spirit, and sleekness of the horses.

5253. *Beans straw* when mixed with peas, Brown considers as affording almost as much nourishment when properly harvested as is gained from hay of ordinary quality; when it is well cut the horses are fonder of it than of peas straw. It should either be given when newly threshed, or else stacked up and compressed by treading or coverings, as the air is found materially to affect both its flavour and nutritive quality.

5254. *The produce of beans in meal* is, like that of peas, more in proportion to the grain than in any of the cereal grasses. A bushel of beans is supposed to yield fourteen pounds more of flour than a bushel of oats, and a bushel of peas eighteen pounds more, or according to some twenty pounds. A thousand parts of bean flour were found, by Sir H. Davy, to yield 570 parts of nutritive matter of which 496 were mucilage or starch 103 gluten, and 41 extract, or matter rendered insoluble during the process.

5255. *The diseases of beans* are, the rust, mildew, black fly or Aphides, and in consequence the honey dews

5256. *Aphides, when they live on beans*, are of a dirty bluish-black colour, similar to those on the elder and cherry. The larvae of the *Coccinella septempunctata*, as well as the perfect insects, devour the Aphides. Several of the small summer birds, viz. largest willow wren middle, and smallest wren, white-throat, lesser white-throat, black-cap, and Dartford warbler, also live on them. The Aphides of beans are brought on by very dry weather: they are most prevalent on the summits of the plants; and some have attempted to mitigate the evil by cutting off the tops. In general, however, the disease is without remedy either preventive or positive. In extreme cases they destroy the leaves, stalks, and fruit: and when this is foreseen, the best thing the farmer can do is to mow the crop or plough it down, and prepare the land for wheat or otherwise, according to the rotation.

SECT. III. *The Tare.* — *Vicia sativa* L. *Draddipha Decandaria* L., and *Leguminosae* J. *Vicia communis de printemps et d'hiver*, Fr., *Wicke* Ger., *Loglio*, Ital. and *Arope*, Sp.

5257. *The tare, vetch, or fitch* (*Vicia sativa*, fig. 742.) has been cultivated for its stem and leaves from time immemorial. It is considered as a native plant, and is found wild also in China and Japan.

Ray in 1686, informs us, that the common tare or vetch was then sown almost all over Europe: that it was chiefly used in England, mixed with peas and oats, to feed horses; but that it was sometimes sown separately for scolding cattle, and was reputed to cause milch cows to yield much milk. The tare, Brown observes, is of hardy growth and, when sown upon rich land, will return a large supply of green fodder for the consumption of horses, or for fattening cattle.

5258. *The varieties of tares* are chiefly two, the winter and spring tare: both have local names, as gore vetch, rath ripe vetch, &c. Some consider them as distinct species, but this is doubtful.

5259. *As the result of an experiment* tried for two years at Bury St. Edmunds, Professor Martyn observes, that there appears a statistical difference in the constitution, if we may so call it, of the two tares in question. Not to say any thing of a trifling difference in the colour and size of their seeds, the only visible mark of distinction seems to be a disparity in the first leaves of the upright stalks, which in the spring

become black, not cooked or softened at the mill, but in the winter tare flour and down to a point. The straw is the valuable which adheres to the hulls, and in this part the bulk of the plants, are the sources both of food. But, whatever the difference may be, it is evident that the straw of the two sorts could do in best expense; thus each acre out of its proper season is found not to prosper.

5260. Some experiments of tares may be obtained by the usual means; and it is thought that some of the numerous species of this plant, which are natives of Europe, might be cultivated with advantage. The French cultivate a variety which they call *Fleur blanche*, or *Leucocarpa* (Gussone, *Fleur blanche* 1836). They substitute among their beans varieties *Plan angustifolia*, *Orléans*, *Paquis-Orléans*, *Orléans*, *Orléans*, and *Orléans*. The *Plan angustifolia* and *Orléans* are cultivated in Germany. Dr Anderson has recommended the *F. alba*, and a writer in *The Book of the Farmer*, the *F. Orlean*. Some species of *Leucocarpa*, *Orléans*, and *F. vicia* might probably also be tried with success.

5261. In choosing between the spring and winter tare, every thing must depend on the intention of the crop. If the object is to have early food, the winter variety is undoubtedly to be preferred, but where the land is foul and requires to be two or three times ploughed in spring, or where a late crop is desired, or a crop for seed, then the spring variety will generally deserve the preference.

5262. The soil preferred by the tare is a clay but they will grow in any rich soil not over dry. In a moist climate, the haulm grows so luxuriant as to rot at bottom; and in one over dry it is deficient in length. A dry season, however, is on the whole more favourable than a moist one, as this crop soon covers the surface.

5263. The preparation of the soil seldom consists of more than one ploughing, if for autumn sowing; and of a winter and spring ploughing, when to be sown in spring. If in the latter case the land is very foul, several ploughings are given, or one ploughing and several stirrings with the out-runner. In general, tares succeed some of the corn crops. In England tares are sometimes given either with a view to cutting them off early and following with a crop of turnips, or to enriching the soil for a crop of wheat.

5264. The time of sowing depends on the kind of tare, and the purposes in view.

5265. The winter variety is sown in September and October; and the first sowing in spring ought to be as early as the season will permit. If they are to be cut green for feeding throughout the summer and autumn, which is the most advantageous method of consuming them, successive sowings should follow till the end of May. Summer tares, when meant for seed, however, ought to be sown early, "otherwise the returns will be imperfect; but when for green food, any time between the first of April and the latter end of May will answer well, provided crops in succession, from the first to the last-mentioned period, be regularly cultivated. Instances are not wanting of a full crop being obtained even when the seed was sown so late as the middle of June, though sowing so late is a practice not to be recommended. In Middlesex, the winter sowings are commenced about the beginning of August. In the northern counties no winter sowings are made, as the tare there will not mature the severity of that season.

5266. The mode of sowing tares is mostly broadcast, which should be performed as evenly as possible over the surface of well-prepared land the seeds being afterwards covered in by proper harrowing, in order to prevent their being picked up by birds, and ensure their perfect vegetation and growth. It has been suggested, however, that, in rich clean soil, it is probable the row-method would succeed well with this sort of crop, which, as Marshall states, is the practice in some of the southern districts of the island. After the seed is sown, and the land carefully harrowed, a light roller ought to be drawn across, so that the surface may be smoothed, and the scythes permitted to work without interruption. It is proper also to guard the field for several days against the depredations of pigeons, who are remarkably fond of tares, and will pick up a great part of the seed, unless constantly watched.

5267. The quantity of seed to an acre is from two and a half to three and a half bushels, according to the time of sowing, and to whether they are to be consumed green or left to stand for a crop.

5268. When tares are intended for seed, less seed is required than when they are grown for spring or for drying the hanks. A writer in *The Farmer's Magazine* (vol. 1.) has suggested, that the most productive method of sowing this crop, when intended for seed, is to mix them amongst beans when drilled, at the rate of one fryot of tare to one boll of beans. From trials made it is ascertained, it is said, that the quality of the tares is vastly improved by being blended with beans, as, by clinging to the latter they are kept from the ground, and enjoy the full benefit of the sun for ripening them in a perfect manner. And they are in this way much earlier harvested than when sown by themselves. They answer, at the same time, for tares to be the principal crop, and the produce may on an average of seasons, be considered as at least double. A little rye sown with winter tares, and a few sets with the spring sort, not only serve to support the weak cropping state of the tares, but add to the bulk of the crop by growing up through the interstices.

5269. As the choice of the seed it is hardly possible to distinguish the grain of the winter from that of the spring variety: the former is supposed to be rather smaller and lighter coloured, but the only reliance must be on the honesty of the vendor. Pump seed, and a sample free from the seeds of weeds, will of course be selected, whatever be the variety.

5270. The after culture given to tares consists merely in pulling out the larger weeds, unless they are in rows, in which case the horse or hand hoe is applied, or intended for seed, in which case weeding must be more particularly executed.

5271. In reaping tares for selling they ought always to be cut with the scythes, as the sickle, by breaking under the stalks, and tearing up a number by the roots, renders the second crop of little value. When mown early, they will in a moist season produce three mowings, but generally two. In reaping tares for seed, they may be either mown or taken with the sickle, and treated like peas in drying, stacking, and threshing.

5272. Tares are eaten off the ground in some places by different kinds of live stock, particularly by sheep; and as the winter-sown variety comes early in spring, the value of this rich food is then very considerable. The waste, however, in this way, even

though the sheep are confined in hatches, must be great; and still greater when consumed by horses or cattle.

5273. *These crops are sometimes made into hay, in which case more attention is found necessary than in those of most of the artificial grasses, as wet is more injurious to them, and they require more sun and air; but in other respects they demand the same cautious management, in order to preserve the foliage from being lost. The time for cutting for this purpose is, according to the author of *The Synopsis of Husbandry*, when the blossoms have declined and they begin to fall and lie flat. When well made, the hay is of the best and most nutritious quality.*

5274. *The produce of tares cut green is, according to Middleton, ten or twelve tons per acre, which is a large crop, and when made into hay about three tons per acre, which shows the disadvantage of making these crops into hay. It is found that the spring tares-crops are lighter, and most liable to be injured by a dry season.*

5275. *The produce in seed is likewise found to be considerable, being by some stated at from three to six sacks, but in other instances forty bushels, or more, have been obtained from the acre.*

5276. *In the application of tares they are found to be a hearty and most nourishing food for all sorts of cattle.*

5277. *Cows give more butter when fed with this plant than with any other food whatsoever. Horses thrive better upon tares than they do upon clover and ryegrass, and the same remark is applicable to the feeding of cattle, which feed faster upon this article of green fodder than upon any kind of grass or succulent with which we are acquainted. Danger often arises from their eating too much, especially when potted; as colics, and other stomach disorders, are apt to be produced by the excessive loads which they devour. Perhaps a great quantity of fixed air is contained in this vegetable; and as heavy crops are very dry at the root when cut, it is not to be wondered that accidents often happen, when the animal is indulged with the unrestrained consumption of them. Were cut straw mixed with the tares in the racks or stalls in which they are deposited, it is probable that fewer accidents would follow, though this assistant is only required when the tares are wet, foul, or over succulent. If the plants are cut green, and given to live stock, either on the field or in the fold-yard, there is, perhaps, no green crop of greater value, not any better calculated to give a succession of herbage from May to November. The winter-sown tare, in a favorable climate, is ready for cutting before clover. The first spring-crop comes in after the clover must be all consumed or made into hay; and the successive spring sowings give a produce more nourishing for the larger animals than the aftermath of clover and may afford green food at least a month longer. In the county of Sussex, Young observes, "tare crops are of such use and importance that not one tenth of the stock could be maintained without them; horses, cows, sheep, hogs, all feed upon them; hogs are sold upon them without any other food. This plant maintains more stock than any other plant whatever. Upon one acre Davis maintained four horses in much better condition than upon five acres of grass. Upon eight acres he has kept twelve horses and five cows for three months without any other food; no artificial food whatever is equal to this excellent plant." This statement must be coupled with the usual produce of turnips in Sussex, 10 or 15 tons per acre, hence the supposed superiority of tares to every other green crop. Tares cut green Professor Thunberg observes, draw no nourishment from the soil whatever, while made into hay they afford a fodder preferred by cattle to pea straw and more nutritive than hay or any other herbage.*

5278. *The use of the grain of tares is generally for reproduction; but they are also given to pigeons, by which they are highly relished, and it is thought they would form a very good food for poultry. In Germany they are given to horses, cows, sheep, and swine.*

5279. *The disease of tares are so few as to be of no consequence. A crop is sometimes, but rarely, lost by mildew.*

#### SECT. IV Various Legumes which might be cultivated in British Farming

5280. *The lentil, kidneybean, and chick pea are grown both in France and Germany, as field plants, for their seeds, which are used as food. They are by no means likely to become articles of general culture in Britain, but it is worth while to know that they may be cultivated here instead of being imported, and also that they form very excellent articles of human subsistence.*

5281. *The lentil is the *Ervum Lens L.* *Lentilium, Fr.* *Lentum, Ger.* and *Lenticula, Ital.* (Ag 743)*

It is a legume of the greatest antiquity being in use in Man's time, and much prized in Eastern countries ever since. In Egypt and Syria, they are parched in a *Syrum-pas* and sold in the shops, and considered by the natives as the best food for those who undertake long journeys. The lentil is considered a native of France, but has been known in England from the earliest agricultural records. In Gerard's time they were sown like tares, their haulm given to cattle, and the seed to pigeons, and used in congee soups.

5282. *There are three varieties of lentils cultivated in France and Germany: the small brown, which is the lightest-flavored, and the best for harlots and soups; the yellowish which is a little larger and the next best; and the lentil of Provence, which is almost as large as a pea, with luxuriant straw, and more fit to be cultivated as a turn than as food for man. The French have also a winter lentil, *Lentillon d'hiver* and they cultivate the *Ervum Brille, Lentille Erve on Bréville* and the *E. monanthos, Lens à une fleur, Jarrois d'Anjou*. The Spanish lentil, *Grain cultivé, Lentille d'Espagne* Fr. *Lenteja*, Span., — is the *Lathyrus sativus* (Ag 744.) It is sometimes grown in gardens in this country, and occasionally in the fields in France. The lentil of Canada, *Lenticle du Canada, Fr.*, is the*

*Vicia platensis L.* (Ag 744.) *Vicia Brille Willd.* *Ervum tetrasperum L.*, and *E. monanthos L.*, are also cultivated in some places as lentils; and indeed the seeds of all the tribe *Vicia* (*Rangosiphia* of Plants, p. 1068.) may be eaten by man.

5283. *A dry warm, sandy soil is requisite for the lentil; it is sown rather later than the pea, at the rate of a bushel or a bushel and a half to the acre; in other respects its culture and harvesting are the same,*

and if these remain. The lentil, *Vicia faba*, is a crop not uncommon about Chester and in Essex, where they sow a bushel an acre on one ploughing in the beginning or middle of March. It is there the custom to make hay of them, or stack them for cutting into chaff for troughment for sheep and horses, and they sow them on both heavy and dry soils. It is, however, added, that the whole country is of a calcareous nature. It is likewise stated, that attention should be paid not to water horses soon after eating this sort of food, as they are apt to have them. They are asserted to be cultivated for the same purposes in Cumberland, and probably in other districts.

3284. The produce of the lentil in grain is about a fourth less than that of the tares; and in straw it is not a third as much, the plants seldom growing above one foot and a half high. The straw is, however, very delicate and nourishing, and preferred for lambs and calves, and the grain on the Continent sold at nearly double the price of peas. Kin-

boof obtained from 3540 parts of lentils, 1580 parts of starch, and 1435 of a matter analogous to animal matter.

3285. The use of the lentil on the Continent is very general, both in soup and dressed with a butter sauce as haricot. They are imported from Hamburgh, and sold in London for the same purpose.

3286. The chick pea (*Cicer arvensium*, Fr. *Cicer arvensium*, Ag. 61.) grows naturally in the south of Europe, and is cultivated there for the same purposes as the lentil, but it is too delicate for field culture in this country.

3287. The induratum (*Phaseolus vulgaris* L.; *Haricot*, Fr.; *Schneidbohne*, Ger.; and *Pigeonpea*, Ind.) is a native of India, but ripens readily in dry summers in most parts of Britain. Its culture has been hitherto confined to gardens, but it might be grown equally well in dry warm, rich, and sheltered soils, being grown in the fields of Germany, Switzerland, and in similar climates. The sort generally used for this purpose is the small dwarf white; the ground is prepared by several stirrings, and the seed is dibbled in rows eighteen inches or two feet asunder in the beginning of May. The ground is hoed and weeded during the summer and the crop is ripe in August. It is usually harvested by pulling up the plants, which, being dried, are stacked or threshed. The haulm is of little bulk or use, but the seed is used in making the esteemed French dish called haricot, which it is desirable the cottagers of this country should be made acquainted with. There is, perhaps, no other vegetable dish so cheap and easily cooked, and at the same time so agreeable and nourishing. The beans are boiled and then mixed with a little salt butter or other fat, and a little milk or water and flour. From 3540 parts of induratum, Kinboof obtained 1805 parts of matter analogous to starch 851 of vegetable animal matter, and 798 parts of mucilage. Haricots and lentils are much used in all Catholic countries during Lent and eveing days, as they from their peculiar constituents, form so excellent a substitute for animal food. During the prevalence of the Roman religion in this country they were probably much more generally used than at present. As reformation are often carried farther than is necessary poultry lentils may have been left off by Protestants, lest the use of them should be considered a symptom of popery.

3288. The white lupine (*Lupinus albus*, Fr.; *Lupinus albus* L. Ag. 746.) was cultivated by the Romans as a legume, and is still occasionally grown in Italy and France. The seeds were formerly and are sometimes now used as food, but more generally the whole plant is sown and given as herbage to cattle, and sometimes the crop is ploughed down as manure.

#### CHAP. IV

##### *Plants cultivated for their roots or leaves in a recent State as Food for Man or Cattle.*

3289. Plants cultivated for their roots or leaves are various, and most of them are adapted both for human food and that of domestic animals, but some are chiefly or entirely grown for the nurture of live stock. The plants which we include under this head, are the potato, turnip, carrot, parsnep, beet, cabbage tribe, lettuce, and chichory. The culture of roots may be considered a branch of farming almost entirely of modern origin, and more peculiarly British than any other department. Turnips were cultivated by the Romans, and in modern times brought into notice as objects of field culture in the last century, but they were most imperfectly managed, and of very little utility in agriculture till their culture was undertaken by the British farmer. The potato, carrot, and parsnep were also first cultivated in the fields of this country. Enriched or light soil, superior pulverisation and manuring, the row-method, and careful after-culture, are essential to the maturation of the plants to be treated of in this Chapter, and hence the importance of such crops as preparations for those of the bread corn.

\*5290. The natural products of these plants are thus given by Sir H. Davy, —

Synonimic Name.	English Name.	In 1000 Parts.				
		Whole quantity of starch or saccharine matter.	Starch or starch.	Saccharine matter or sugar.	Gluten or albumen.	Amount of water or moist matter, dried, heated, and distilled.
<i>Solanum tuberosum</i>	Potato	From 800 to 900	From 200 to 150	From 50 to 15	From 40 to 30	
<i>Solanum vulgare</i>	Red beet	148	14	121	13	
<i>Solanum elaeagnifolium</i>	Mangold wurzel	125	15	110	4	
<i>Betula alba</i>	Common turnip	42	7	34	1	
<i>Betula alba</i> var. <i>rutabaga</i>	Swedish turnip	42	9	31	2	
<i>Daucus Carota</i>	Carrot	98	3	95		
<i>Festuca ovina</i>	Fennel	99	9	90		
<i>Brassica oleracea</i>	Cabbage	75	41	34	8	

Sacra. L. The Potato. — *Solanum tuberosum* L. *Penstemon Monogynus* L., and *Solanum J. Pomme de Terre*, Fr., *Cartoffel*, Ger., *Tartufflo* or *Pomo di Terra*, Ital. and *Batata*, Span.

\*5291. The potato is ascertained to be a native of South America, having been found wild both in Buenos Ayres and in Chili though Humboldt was very doubtful if that could be proved. He admits, however, that it is naturalised there in some situations. Sir J. Banks (*Hort. Trans.* vol. 1. p. 8.) considers that the potato was first brought into Europe from the mountainous parts of South America, in the neighbourhood of Quito, where they were called *patas*, to Spain, in the early part of the sixteenth century. From Spain, where they were called *batatas*, they appear to have found their way first to Italy where they received the same name with the truffle, *taratuffa*. The potato was received by Clusius, at Vienna, in 1588, from the governor of Mons, in Hanault, who had procured it the year before from one of the attendants of the Pope's legate, under the name of *teratufflo* and learned from him that it was then in use in Italy. In Germany it received the name of *cartoffel*, and spread rapidly even in Cluvius's time.

\*5292. The English potato was brought from *Fergana* by the colonists sent out by Sir Walter Raleigh in 1584, who returned in July 1586, and "probably" according to Sir Joseph Banks, "brought with them the potato." Thomas Herriot, in a report on the country published in De Bry's *Collection of Voyages*, (vol. 1. p. 17) describes a plant called *opemank* (not *opemank* as in the *Hort. Trans.*, with "roots as large as a walnut, and others much larger" they grow in damp soil, many hanging together, as if fixed on a tripod. They are good food, either boiled or roasted. Gerard, in his *Herbal*, published in 1597, gives a figure of the potato, under the name of the *potato* of *Fergana*, whence, he says, he received the roots and this appellation it appears to have retained in order to distinguish it from the batatas, or sweet potato (*Convolvulus Batatas*), till the year 1640, if not longer. "The sweet potato," Sir Joseph Banks observes, "was used in England as a delicacy long before the introduction of our potatoes. It was imported in considerable quantities from Spain and the Canaries, and was supposed to possess the power of restoring decayed vigour. The lasting contents of batatas, and other confections of similar unwholesome qualities, which our ancestors were duped, were principally made of these and of eringo roots."

\*5293. The potato was first planted by Sir Walter Raleigh, on his estate of Youghall near Cork, and, Gough says, was "cherished and cultivated for food in that country before its value was known in England." Sir though they were soon carried over from Ireland into Lancashire, Gerard, who had the plant in his garden in 1597 under the name of *Solanum virginicum*, recommends the roots to be eaten as a delicate dish, not as common food. Jarkinson mentions, that the tubers were sometimes roasted and steeped in sack and sugar or baked with marrow and spices, and even preserved and candied by the confectioners. There is a tradition among the peasantry in the county of Galway that the potato was introduced there previous to its being known in any other part of Ireland, owing to a vessel with some of the roots on board having been wrecked on their coast, and a few of the roots having been roasted by children who found them; they were so much approved of, as to induce the planting of the remainder.

\*5294. For encouraging the cultivation of potatoes, with the view of preventing famine, the Royal Society took some measures in 1688. Still, however, although their utility as an article of food was better known to no high character was bestowed on them. In books of gardening, published towards the end of the seven-teenth century a hundred years after their introduction, they are spoken of rather slightly. "They are much used in Ireland and America as bread," says one author, "and may be propagated with advantage to poor people." — "I do not hear that it hath been raised," are the words of another "whether they may not be propagated in great quantities, for food for swine or other cattle." Even the enlightened Dr. Swift seems to have entertained a prejudice against them. "Plant potatoes," he says, writing in 1688, "in your worst ground. Take them up in November for winter spending. There will enough remain for a stock, though ever so much pestered." But the use of potatoes gradually spread, as their excellent qualities became better understood. It was near the middle of the eighteenth century however, before they were generally known over the country, since that time they have been most extensively cultivated. In 1766, it was found that, in the county of Essex alone, about 1700 acres were planted with potatoes for the supply of the London market. This must form, no doubt, the principal supply. But many fields of potatoes are to be seen in the other counties bordering on the capital, and many ship-loads are annually imported from a distance. In every county in England, it is now more or less an object of field culture.

\*5295. Potatoes, as an article of human food are, next to wheat, of the greatest importance in the eye of the political economist.

\*5296. From another eye that can be cultivated with the public derive so much food as from this valuable produce; and it admits of demonstration, that an acre of potatoes will feed double the number of able persons; and it admits of demonstration, that an acre of potatoes will feed double the number of people that can be fed from an acre of wheat. Potatoes are also a nourishing and healthy food, mixed by almost every palate; and it is believed there is hardly a dinner served up six months in the year without them, in any part of the kingdom. Notwithstanding all these things, and they are of great importance in one point of view, we are doubtful whether potatoes can be placed so high in the scale as

They require a great deal of manure, while, generally speaking, little is returned by them; they are a heavy manure for fields, turnstumps in the spring and during summer, and interworking with the seed sowing of wheat, the most important use to him; even from particular circumstances, they cannot be worked without when taken in the vicinity of large towns: hence they are in most respects an indispensable article. As the farmer, the real criterion is the profit which potatoes will return in feeding hogs; and here, we apprehend, the result will altogether be in favour of turnips, and rutabagas, as the most profitable articles for that purpose.

5297. *Potatoes of the past, or Northern potato*, was formerly considered of importance to the farmer as an addition to his corn crop, or rather a substitute, which is of material benefit when turnips are seasonably, but as this variety cannot be used as human food, the extension of its culture cannot be recommended. By substituting any of the good spring sorts for the use of cattle, a succedaneum may be had for the human species in years of scarcity.

5298. *The value of potatoes as a fallow crop, and as an article of food for cattle compared with turnips and cabbages for the same purposes*, Marshall observes, may be considered thus —

5299. *Potatoes are more nutritious*; and, in the opinion of those who have used them, fatten cattle much quicker than either turnips or cabbages. Potatoes, too, being sown from the previous of winter are a more certain article of feeding than turnips or cabbages — both of which are liable to perish under an alternation of frost and thaw — and the turnip, more particularly is looked up, or rendered more difficult to be come at, during a continuance of snow or frost. Turnips and cabbages, if they out-weather the severities of winter, occupy the soil in the spring when it should be prepared for the succeeding crop while potatoes, if properly laid up, are a food which may be continued without inconvenience until the cattle is finished, or the ground has acquired the requisite heat for finishing them in the field. On the other hand, potatoes are a disposable crop to cultivate the planting is a tedious dirty business and taking them up may be called the filthiest work of husbandry especially in a wet autumn. A powerful argument for the extensive culture of potatoes as food for live stock is, that in seasons of scarcity they can be adapted as human food. Here, as in many other points, the opinion of Marshall and other English agriculturalists is rather at variance with that of the Northumbrians and Northwicks. In Northwicks and Northwicks, a crop of potatoes is often taken before turnips, by means of which the land is restored to a fertile state.

5300. *The varieties of the potato are innumerable* — they differ in their leaves and bulk of haulm; in the colour of the skin of the tubers; in the colour of the interior compared with that of the skin; in the time of ripening in being farinaceous, glutinous, or watery in tasting agreeably or disagreeably in cooking readily or tediously; in the length of the subterraneous stolones to which the tubers are attached; in blossoming or not blossoming; and, finally, in the soil which they prefer.

5301. *The earliest varieties of the potato are chiefly cultivated in gardens, and therefore we shall only notice such early sorts as are grown in the fields.* — These are —

The early Midon.

The monarch.

The early show and

The early champion.

The last is the most generally cultivated round London. It is very prolific, hardy and ready. Early varieties, with local names, are cultivated near most large towns, especially Manchester, Liverpool, Glasgow, Edinburgh, and the metropolis.

5302. *The late field varieties in most regions are —*

The old-fashioned Midon.

Large Midon.

Small Dutch potato in 1830, from seed, and obtained one of the best field potatoes, being white, nearly well sized, and prolific.

Landmark pink eye, good.

Black skin, white interior and good.

Purple, very early, productive, and keeps well.

Red apple, nearly, leaves the longest of any. Turnips, or purple and white skinned, an excellent Scotch potato, prolific, nearly amazingly well sized, and keeps well.

5303. *The varieties grown exclusively as food for live stock are —*

The York or Northern potato large, and seed white skinned, and the smaller skinned with red. Neither disposable, and not much fit to make of its being used as human food. It succeeds best on heavy lands.

Two or three large, yellow skinned and within, very prolific, and fit to eat.

The late champion; large and prolific, white skinned, and may be used as human food.

5304. *New varieties of potatoes are procured with the greatest ease.* The following directions are given in a useful work on this plant. — Pluck off the spuds when the stalk has ceased to vegetate and is drying up. The seed being then fully ripe, break the apple in a hair sieve, wash the pulp clean from the seeds, and dry them in the sun, then sow the seed in beds in March, and take the potatoes up in October. They will attain the size of turnips, or at most be no larger than walnuts. Select the finest and best, and keep them secure from frost by thoroughly drying, and interworking, and covering them with sifted wood or coal-ashes. Plant them in April following, at the distance of fifteen inches asunder — and when the plant is two inches high, hill them with fresh earth. This may be done several times, constantly taking care to keep them clear from weeds. Observe when the stalks decay — some will be found decaying much sooner than others — these are the early kinds, but those that decay last are the sorts which come late. Take them up in rotation as they ripen, and let the produce of each potato be kept separate till the next year. Such as decay early may be used as soon as they are taken up, by dressing one or two — should they be approved, the remainder may be preserved, but those which are late should not be tried before January or February, for it will be found that the late kind of potatoes, newly raised, are very soft, and not like seed, until they have been hoarded a certain time, when they become mealy. Under each stalk you may expect to find a gallon of potatoes — those planted the third year may, perhaps, produce two bushels — and their produce afterwards will be very considerably greater. Thus if taken full three years to form an adequate judgment of potatoes raised from seed — and, after all, if one is too much so as to be worth preserving, it is as much so can be suitably expected. In general, the produce of the seed will resemble the parent stock; but varieties will give both white and red offspring, and among the offspring of kidneys will be found round shaped tubers. One great advantage of raising varieties from seed is alleged to be the improvement of the vegetable principle.

5305. *Some of the earlier sorts of potatoes do not blossom, and consequently do not, under ordinary management, produce seeds.* To procure blossoms and seeds from them, it is necessary, from time to time, during the early part of the summer to remove the earth from the roots of the plants, and pluck off the tubers in potatoes as they begin to form. By thus preventing the strength of the plant from being employed in forming tubers at the root, it will flow into the leaves and stalks, and produce blossoms and seeds. Perhaps, the greatest of the Northumbrian society, by adopting this practice, succeeded in procuring seeds from three early potatoes which had never before produced blossoms — and from these seeds he raised numerous varieties, some heavy and low early, others small and very early. He further improved the blossoms produced by these early potatoes with other sorts, some early and some late (in the way in which gardeners clear the heads of cattle to improve the offspring), and he succeeded in producing varieties, some early than late sorts, and more heavy and prolific than his early potatoes he had seed.

There is objection in his field, deeming them preferable to all other sorts as admitting of later planting and earlier sowing; and this practice he justly considered as highly favourable to the succeeding crop of wheat.

3306. In choosing a sort or sorts of potatoes from the numerous varieties which are to be found every where, perhaps the best way is, for the cultivator to procure samples and taste them, and to fix on what best pleases his palate. This may be one of the best early potatoes for general field culture; and the Kidney and Liverpool are good sorts to come in in succession. The Lancashire pink is also an excellent potato; and we have seen in any part of the British Isles tasted a potato equal in sweetness and flavour to this variety, as cultivated round Prescot, near Liverpool. The red apple and tartan are of undoubted preference as late or long keeping potatoes. The yam is probably the best potato for stock, and will produce from twelve to fifteen tons per acre.

3307. The soil in which the potato thrives best is a light loam, neither too dry nor too moist, but if rich, it is so much the better. They may, however, be grown well on many other sorts of lands, especially those of the mossy, moory, and similar kinds, where they are free from stagnant moisture, and have had their parts well broken down by culture, and a reasonable portion of manure added. The best-flavoured table potatoes are almost always produced from a newly broken up pasture ground not manured, or from any new soil, as the site of a grubbed up copse or hedge, or the site of old buildings or roads. Repeated on the same soil they very generally lose their flavour. The yam produces the largest crops on a loamy and rather strong soil, though it will grow well on any that is deeply ploughed and well manured.

3308. In preparing the soil for potatoes. It is of much importance to free it as completely as possible from root weeds, which cannot be so well extirpated afterwards, as in the culture of turnips, and some other drilled crops, both because the horse-hoe must be excluded altogether at a time when vegetation is still vigorous, and because at no period of their growth is it safe to work so near the plants, especially after they have made some progress in growth. It is the earlier time of planting, and of finishing the after culture, that renders potatoes a very indifferent substitute for fallow and in this respect in no degree comparable to turnips. For this reason, as well as on account of the great quantity of manure required, their small value at a distance from large towns, and the great expense of transporting so bulky a commodity the culture of potatoes is by no means extensive in the best managed districts. Unless in the immediate vicinity of such towns, or in very populous manufacturing counties, potatoes do not constitute a regular rotation crop though they are raised almost every where to the extent required for the consumption of the farmer and his servants, and, in some cases, for occasionally feeding horses and cattle, particularly late in spring. The first ploughing is given soon after harvest, and a second, and commonly a third, early in spring; the land is then laid up into ridges from twenty-seven to thirty inches broad, as for turnips, and manured in the same manner.

3309. The best manure for the potato appears to be litney farmyard dung and the best mode of applying it, immediately under the potato sets. Any manure, however, may be applied and no plant will bear a larger dose of it, or thrive in clearer or less prepared manure even dry straw, rushes, or spray of trees may be made use of with success. It is alleged, however that recent horse manure, salt, and soapstone ashes, have a tendency to give potatoes a rank taste, and to render them scabby.

3310. The best climate for the potato is one rather moist than dry and temperate or cool, rather than hot. Hence the excellence of the Irish potatoes, which grow in a dry loamy calcareous soil, and moist and temperate climate and hence, also, the inferiority of the potatoes of France, Spain, and Italy and even Germany. In short, the potato is grown nowhere in the world to the same degree of perfection as in Ireland and Lancashire, and not even in the south of England so well as in Scotland, and the north and western counties all which is, in our opinion clearly attributable to the climate.

3311. The season for planting potatoes in the fields, depends much on the soil and climate. Where these are very dry, as they always ought to be for an early crop, the sets are usually put in the ground in March or earlier, but for a full crop of potatoes, April is the best time for planting. Potatoes, indeed, are often planted in the end of May and sometimes even in June but the crops, although often as abundant, are neither so mellow nor mature as when the sets are planted in April, or in the first eight or ten days of May. For seed, however they are preferable.

3312. In preparing the sets of potatoes, some cultivators recommend large sets, others small potatoes entire, and some large potatoes entire. Others, on the ground of experience, are equally strenuous in support of small cuttings, sprouts, shoots, or even only the eyes or buds. With all these different sorts of sets, good crops are stated to have been raised, though tolerable-sized cuttings of pretty large potatoes, with two or three good eyes or buds in each, are probably to be preferred.

3313. Independently of the increased expense of the seed, it is never a good practice to make use of whole potatoes as sets. The best cultivators in Ireland and Scotland invariably cut the largest and best potatoes into sets, rejecting, in the case of kidney potatoes, the root or nearly end, and as having no heel and the top or watery end as having too many. No objection is made to two, or even three buds on each set, though one is considered sufficient. A very slight scarcity of common sense might have saved the advocate for shoots, sprouts, eyes, &c., their experiments and arguments; it being evident, as Brown has observed, to every one with any practical knowledge of the nature of vegetables, that the strength of the stem at the crown depends in direct proportion upon the vigour and power of the set. The set, therefore, ought to be large, nearly smaller than the fourth part of the potato and if the potato is of small size, one half of it may be profitably used; at all events, rather err in giving over-large sets, than in making them too small; because by the first error no great loss can be sustained; whereas, by the second a double and late crop may be the consequence. It is maintained beyond doubt in Lancashire, Cheshire, and other counties in the north and west of England, that sets taken from the top or watery end of the potato, planted at the same time with sets taken at the root or nearly end, will ripen their tubers a fortnight sooner. It is asserted also, and accounted for on the same general principle, that the plants raised from sprouts tubers are both vigorous and more early than such as are raised from tubers perfectly ripe. (See Gard. Mag. vol. ii.) But these assertions always do not come down before planting, that the wounds may dry very hot in warm weather, and thus perishing this operation several weeks or months beforehand, provided the sets are not exposed too long to the drought so as to deprive them of their natural moisture.

3513. The quantity of sets depends on the size of the potatoes: in general, where the sets are sufficiently large, three bushels will be required for an acre; more than ten for pines, and fewer than eight for the thin early sorts and sub-varieties.

3514. The modes of planting the potato are various.

3515. When small varieties are employed, they are very frequently planted on beds (previously long-beds, or four or six feet wide, with a ditch or gutter of a foot or eighteen inches in width between, which carries off the surplus of the surface). This is the richest mode of planting and cultivating potatoes, and superiority of being laid out either on a down or in a garden. The next mode is planting on a plain surface, either with or without manure, according to the state of the soil. Here the sets are planted in rows, with a distance of from eighteen inches to two feet and a half between the rows according to the kind of potato, and about four to six inches in the row. In planting, a hole for each set is made by a stick with a spike, while a woman or boy draws the set, and the earth is replaced, or the potato ditch is trowled, and the ground afterwards deeply harrowed. Another mode of planting is on a wide surface, where the soil is inclined to be dry is in some cases practised, which is, after the land has been brought into a proper condition by ploughing over twice or oftener and well harrowed, to spread the manure regularly over the whole surface, the sets being planted in every third furrow and the dung with the fine earth turned upon them by the next furrow of the plough. In this way the manure is however placed upon the sets, which has no comparison just fully shown to be superior to the produce. Besides, from the whole of the surface of the ground being covered with dung, a considerably larger proportion must be required than when deposited only in the drills, and of course the crop cannot be cultivated to advantage in that respect.

3516. In planting the potato on sword land, after it has been prepared by the use of a plough that just turns off the surface, it is sowed by the farmer, or is sowed by himself to place the sets upon the inverted sod, and cover them with the loose mould from below by means of a common plough, or the trench plough may be used with perhaps more advantage, but a better method is that of paring and harrowing. In some cases the practice is, however, to turn down the turf with or without manure, and then to put in the sets by a dibble though the former is probably the better practice, as the turf material on which the sets are put soon begins to decay, and the purpose of a manure is in some measure answered by it. It is a plan that may be adopted with advantage where manure is scarce, as in bringing waste and other coarse grass lands into the state of preparation for grain crops.

3517. A mode of planting potatoes and at the same time trenching the land, is practised in Lancashire, and in some districts in the north-east of Scotland. The farmer having carried the dung, and laid it on the field in heaps, at proper distances, the operation is performed by the manufacturers and people who rent the field, and in the following manner:—Across the end of the ridge a trench is formed, about three feet wide, and from ten to fourteen inches deep, according to the depth and quality of the soil. That being done, a second trench of the same breadth is marked off, and the surface-soil, to the depth of six or eight inches, is thrown into the bottom of the former trench, over which a sufficient quantity of dung being laid, the potatoes are planted at the distance of eight or ten inches from each other and then as much earth is taken from the bottom of the second trench as is necessary for covering the potato sets, and making up the first trench to its former level. Thus the field being completely trenched well manured, and kept thoroughly clean by repeated hand-hoeing, would not only produce an abundant crop of potatoes, but must also be in high condition for receiving whatever kind of seed may be afterwards sown.

3518. The mode of planting potatoes practised by the best farmers of the northern districts, is in drills formed by the plough in the same manner as in preparing the land for turneps. The soil is laid up into ridges from twenty-seven to thirty inches broad, the manure is distributed between them, and on this manner the sets are placed from four to eight inches asunder: they are then covered by reversing the ridges.

3519. The planting of early potatoes is carried to a very high degree of perfection in Lancashire. It is stated in *The Lancashire Agricultural Report*, in respect to the raising of seed potatoes, that upon the same ground from which a crop has already been taken, the early seed potatoes are in some places after a single clearing, and after being got up about November are immediately cut up into sets and preserved in cut beds or saw-dust, where they remain till March when they are planted, after having had one sprout taken off, which is also planted. The sprouts are of a length sufficient to appear above ground in the space of a week. But the most approved method is, to cut the sets, and put them on a room door where a strong current of air can be introduced at pleasure the sets held thinner as about two levers in depth and covered with the like materials (chaff or saw-dust) about two inches thick. This screens them from the winter frosts, and keeps them moderately warm, causing them to vegetate, but at the same time admits air to strengthen them, and harden their shoots, which the cultivators improve by opening the doors and windows on every opportunity afforded by mild soft weather. They frequently examine them, and when the shoots are springing an inch and a half, or two inches, they carefully remove one half of their covering, with a wooden rake, or with the hands, taking care not to disturb or break the shoots. Light is requisite, as well as air to strengthen and establish the shoots. On which account a green house has the advantage of a room, but a room answers very well with a good window or two in it, and if to the sun still better. In this manner they suffer them to remain till the planting season, giving them all the air possible by the doors and windows, when it can be done with safety from frost: by this method the shoots at the top become green, leaves are springing, and are moderately hardy. They then plant them in rows in the usual method, with a setting-dick, and carefully fill up the cavities made by the setting stick by this method they are enabled to bear a little frost without injury. The earliest potato is the superline white kidney; from this sort, upon the same ground, have been raised four crops, having sets from the top of the first ready to put in as soon as the others were taken up, and a fifth crop is sometimes raised from the same lands, the same year of transported winter lettuce. The first crop had the advantage of a covering in frosty nights. It is remarked that this useful information was communicated by J. Hindell, Ormskirk, and has hitherto been known only among a very few farmers.

3520. As the earliest part of Lancashire the early potato is cultivated in the fields in warm situations, and brought to market in the end of May and during June. The chief sorts there grown for this purpose are, the Lady's finger or early Kidney, and the early round potato. The cultivators, aware that the buds from the root and top end of the tuber germinate at different periods, sort their sets in the following manner:—The sets near the top end (see fig. 747 a) are found to come to maturity a fortnight earlier than those at the root end (b) and these, therefore, form two classes of sets for an earlier and a later crop. The sets from the middle (c) are put together for an intermediate crop. The sets are planted in the month of March or beginning of April, in drills of twenty-four inches in twenty yards, in the following manner:—

After the drills are formed (see fig. 748 a), loose earth is brushed with a spade or harrowed down, to the depth of six inches, in the interval between them (b) dung is then placed over this loose earth, to the depth of four or five inches (c); the potato sets of the earliest degree (see fig. 747 a) are then laid on the manure, at four or five inches apart, for the early crop; and sets of the second degree (see fig. 747 b), at from six to eight inches apart, for the later crop; and so on. The sets for the early crop are then covered with a spade, to the depth of two inches, and subsequently covered, at two or three different times, to the depth of about five inches. The second and third crops are usually covered with the plough

Some lay the potatoes intended for plants early in the year, before they are wanted to be cut, loose and separate in straw, or on warm boarded floors, and others put them on flakes or frames, in warm situations near the fire, for the same purpose, in order that they may sprout. And when so sprouted to the length of half an inch or an inch, they are then carefully cut as described, sorted, and planted. (*Gard. Mag.* vol. i. p. 407.)

5323. In the north of Lancashire the potatoes are removed from their winter quarters in the last week of January and spread out on a floor or placed on shelves in a room where a fire is kept, or in an upper room of a warm house. On the 2d of February they are covered with a blanket or woolen cloth for about four weeks, which is then taken off in order to harden the sprouts. Towards the latter end of March the sprouts will be found about two inches long and, if they are carefully set, the potatoes will be ready in seven or eight weeks afterwards. Some bring the sets forward by spreading them out and slightly covering them with light mould under the stage or on the shelves of a greenhouse or in a cucumber frame, or in a loft over a stable or cow house. (*Gard. Mag.* vol. ii. p. 43.)

5324. In Dorsetshire the early potatoes cultivated are the Foxley, the Nelson, and the Rufford Kidney Potatoes intended for sets the following year are taken up before they are ripe, just when the outer skin peels off, and before the stalk or stem begins to wither. They are then laid upon a gravel walk, or any dry surface fully exposed to the sun, they remain in that situation for a month or six weeks, when they become quite green and soft, as if roasted, and often much shrivelled; they are then put away in a cellar or pit, where they will remain dry and neither invaded by frost nor much heat. In February they are examined and every eye being then generally found full of long sprouts, they are fit to be planted. The tubers are therefore cut, seldom into more than two sets, viz. the eye or top part, which is planted by itself, and found to come a fortnight earlier, and the root or bottom part, which succeeds them. (*Gard. Mag.* vol. i. p. 172.)

5325. In gardens in the south of England potatoes are planted in a warm border from the first week of October till the latter end of November. They are placed nine or ten inches under the surface and well covered with dung. About the latter end of March they begin to appear above the surface when the ground is deeply hacked with a mattock, and made very loose about the plants; then in a fortnight or three weeks more the surface again, but the plants need not be earthed up unless they are very much exposed to the wind, when a little may be drawn about them to keep them steady. By this method fine ash leaved kidney potatoes may be gathered by the 12th or 15th of May even in situations not very favourable for early crops, and nearly three weeks earlier than they can be gathered from sets planted in the same situation in the latter end of February; and if ordinary care is taken in planting, no danger need be apprehended from the frost. (*Gard. Mag.* vol. vi. p. 50.) Every farmer knows that, among the corn raised after a crop of potatoes, potato plants will be found which can only have sprung from tubers preserved there all the winter in consequence of having been buried by the plough deeper than the frost could reach. It is evident, therefore, that this garden mode of raising a crop of early potatoes might be adopted in the field more especially where the soil was dry, but the success would depend entirely on the deep pruning or grubbing of the soil between the rows a early in spring. Thus might be done to the same degree of perfection as in the garden by the excellent implements of Wilkie or Kirkwood. (1822. and 1825.)

5326. In Cornwall early potatoes are planted in October, spring up a few weeks afterwards, are ready before the autumnal frost stops their growth, and the soil being covered with litter to exclude the frost, they are begun to be used about the end of December and continue in use till May when they are succeeded by the spring planted crops. Of late years Covent Garden market has received supplies of early potatoes from Cornwall, treated in the above manner. (*Gard. Mag.* vol. ii. v. vi.) Early potatoes, when they first come through the ground, are liable to be injured by spring frosts but there is an easy and effectual remedy to every cultivator who will take the trouble, and that is to water them so as to draw off the frost before sunrise. In Ayrshire, where even late potatoes are liable to this injury, acres are sometimes so watered on a single furrow all the hands being called to business by the break of day and the water being sprinkled on the young sprouts, from vessels of any sort, by means of a handful of straw a garden-pot and rose would of course answer better.

5327. The after culture of potatoes consists in harrowing hoeing, weeding, and earthing up.

5328. All potatoes require to be earthed up, that is, to have at least one inch in depth of earth heaped on their roots, and extending six or eight inches round their stem. The reason of this is, that the tubers do not, properly speaking, grow under the soil, but rather on, or just partially buried in its surface. A covering of earth therefore, is found, by preserving a congenial moisture, greatly to promote their growth and magnitude, as well as to improve their quality by preventing the potatoes from becoming green on the side next the light. The earth may be thrown up from the trenches between the beds by the spade or where the potatoes are planted in rows, the operation may be performed with a small plough drawn by one horse, or by the hoe. In Scotland where the potato is extensively cultivated by the farmer as food for cattle as well as man, the plough is universally used. In Ireland, where the bed, or lay bed, manner is adopted, the earth is thrown up from the intervening trenches. The hoe is generally used by market-gardeners.

5329. The after culture, where potatoes are planted in ridges, as above described (5319), commences when the plants begin to rise above the surface. They are then harrowed across, and afterwards the horse hoe, or small hoeing plough and the hand-hoe are repeatedly employed in the intervals, and between the plants, as long as the progress of the crop will permit, or the state of the soil may require. The earth is then gathered once, or oftener, from the sides of the intervals towards the roots of the plants, after which any weeds that may be left must be drawn out by hand, for when the radicles have extended far in search of food, and the young roots begin to form, neither the horse nor hand-hoe can be admitted without injury.

5330. The after-culture adopted in some parts of Devonshire is somewhat singular and deserves to be noticed. The sets are there generally cut with three eyes, and deposited at the depth of three inches with the spade or dibble when the first shoot is three inches high, prepare a harrow with thorns interwoven between the tines, and harrow the ground over till all the weeds are destroyed, and not a shoot of the potatoes left. It may seem strange that such an apparent destruction of a crop should cause an increase, but it may be affirmed as an uncontested fact, that by this means the produce becomes more abundant. The reason appears to be this, although three eyes are left to a piece of potato, one always vegetates before the others, and the first shoot is always single, but being broken off, there is for the present a cessation of vegetation. The other eyes then begin to vegetate, and there appear fresh shoots from the broken eye, so that the vegetation is trebled, the earth made loose, and the lateral shoots more freely expanded. If these hints are observed, the produce of potatoes, if it will, will exceed a fifth of the crop obtained by the usual mode of cultivation.

8322. The culture of potatoes in the district of Kings is that given by an intelligent writer in the Transactions of the Highland Society.

8323. The seed is generally sown as early in spring as possible and that at least twice. In cases where the first ploughings do not sufficiently pulverise the ground, it receives a third, and after every ploughing is well harrowed. The greatest attention ought always to be given to these preparatory operations.

8324. The ground being now prepared, and the season for planting arrived, drills are made for receiving the seed with the common plough. These are drawn about two feet asunder and three inches in depth. The first rows of them are all drawn from one end of the field, the plough returning out of work from the other end, in order to afford time and room for the operation of putting in the seed, and also the dung, where this last operation is rendered necessary. By the time the ploughman has drawn three of these shallow drills or furrows, the persons in charge of the seed begin to plant the first of them, laying each plant at a distance of from nine to ten inches. These are followed by others who put the dung on the top of it, in the case already mentioned, where the manure is to be put into the drill. The ploughman, having completed seven of these drills, may now proceed to return by ploughing to the depth of seven inches between the first and second drills, so as to cover the seed in the first. He then opens another of the shallow drills of three inches, at the distance of two feet, as before mentioned, from the last which he had made, being the seventh, and returning back, he makes another of the seven inch deep furrows between the second and third rows of seed, which covers the second, returning, he opens another seed-drill, and back again a deep one, between the third and fourth rows of seed, which covers the third row, and so on from each end of the field. In this manner the drilling and planting will proceed, without any interruption or interference the one with the other, the plough having at first attained a sufficient distance from the planters to have always a drill open before they can overtake it. The great advantage of placing the seed so much nearer the surface than the deeper furrow alongside of it is, that it is more effectually preserved from the bad effects of wet or damp, consequently less liable to be injured by frost, and it springs sooner.

8325. In this state the field is allowed to remain from a fortnight to three weeks when it is cross harrowed to a perfect level. Afterwards, as soon as the drills can be distinguished by the potatoes shooting above the ground, the plough is again applied, and the drills are formed as before. But in doing so, the plough is taken as close as possible to the plant upon both sides. On one side the plough is lightly put in but on the other it is forced so deep as possible, harrowing the soil over on its neighbouring row of seed, filling up the vacuum which the plough had previously left at it, and forming at the same time a ridge, as it was originally on the top of the plant. What is thus ploughed in the forenoon is cross harrowed completely level during the same afternoon. The great advantage which I apprehend to be derived from this process is the loosening of the soil, destroying the weeds, and the saving of hand-labour. I am satisfied from my own particular experience and observation, that this mode of treating the young growth of the potato is far preferable to any other I have seen practised, either here or elsewhere, however fondling the rough usage thus given to the young plant may appear to one inexperienced in this particular mode of cultivating it.

8326. As soon as the weeds begin to appear the plough is again introduced, which, in the idiom of this country is called "taking from the potatoes," which is done by running pretty close to the plant on both sides, so that a slight ridge is thrown up between the line of plants, and in this situation they remain for eight days, when the plant is "put to" by again re-planting the plough between the rows, and separating the earth concealing the middle ridge above mentioned towards the plant on each side, but without covering it. After this, the process of "putting to" of earth is continued as the plant grows, and takes place at least twice, until the stems are so high that a single horse going among them may seriously injure them. The "putting to" will now be understood as a deeper insertion of the plough in the middle of the drill. The wheels of the labour of ploughing, drilling, taking from, and "putting to" the potatoes, as above described, is performed with the common plough. (Highland Soc. Trans. vol. viii. p. 68)

8327. The field culture of the potato in Argyllshire is thus given by an experienced cultivator in the Gardener's Magazine. The manure is sometimes applied to the field during winter and ploughed in, or it is by the better economists reserved till the field is drilled for planting. When the first plan is adopted, another ploughing is given across the field, which is then covered by the return of the plough along the furrow of which the seed is placed, and then covered by the return of the plough. The best way is to prepare the field in the same way as for turnips, and place the dung in the drill, and the seed on it (fig. 749. c) and then cover them up by clearing down the ridgelet, and forming others (b) a fortnight or so afterwards, the whole field is harrowed across (c). As soon as the plants have so far sprouted that the drill can safely be used from end to end (d) then the whole field is drilled again, as at first, with a very strong harrow (e) and then the harrows are set immediately to work after the plough has finished drilling and the field is levelled again (f). Any one that is unacquainted with the system would suppose the crop ruined, but it is far otherwise. The after-culture is no way different from the common practice of paring away the earth, drill harrowing and earthing up, as in other countries. It is advisable only to pare or earth as the case may be, one side of the drill at each turn, as, by this means, the operations are sooner performed at the time the earth can be more frequently stirred and at the same expense. The charm of this system consists in the additional drilling up and harrowing down by the harrowing, all the larger clods are thrown to the furrow where they are fully pulverised by the drill harrow and after culture, and all the weeds are so effectually drawn from between the plants that there is no use of hand-weeding. The expense may be calculated at less than a third of hand-labour, from the effect and expedition, of course, dry weather is the time for the second drilling and cross harrowing to be performed. (Gard. Mag. vol. vi. p. 314.)

749

The diagram consists of seven horizontal cross-sections of a potato field, labeled (a) through (g), illustrating the sequence of agricultural operations. (a) shows a field with rows of potato plants and a central ridge. (b) shows the field after a second ploughing, with the central ridge covered and new ridges formed on either side. (c) shows the field after being harrowed across, creating a level surface. (d) shows the field after being drilled again from end to end. (e) shows the field after being harrowed with a strong harrow. (f) shows the field after being levelled again. (g) shows the final state of the field, with the plants well established and the soil levelled.

750. Pruning off the ends of the potato blossom is a part of after-culture not attracting the attention of the farmer. This may at first sight appear too minute a matter to enter into the economy of farm management. But when it is considered that the seed is the essential part of every plant, and that to which the ultimate effects of nature are always directed, it will be allowed that an important part of the maintenance of every vegetable must be devoted to this purpose. In the case of the potato, every person knows that the weight of the potato-plant, grown by a single plant, is very considerable. Now we have seen (8324) that apples may be produced instead of tubers in early potatoes, whence it may justly be inferred, that more tubers may be produced in late ones by preventing the growth of the apples. Such was the reasoning of Kings, and, by repeatedly making the experiment, he came to this conclusion, that in ordinary cases of field culture, by pinching off the blossoms of late crops of potatoes, more than one ton

per acre of additional tubers will be produced. The experiments are related in the second volume of *The Horticultural Transactions*, and the practice is similar to one common among the growers of bulbous roots in Holland, as alluded to by Dr Darwin, who also recommends its application to the potato. A woman or boy will crop the blossoms from an acre of potatoes in a day or even in less time, when the crop is not excessively luxuriant.

5938. *The taking of the crop of potatoes on a small scale is generally performed with the spade or three-pronged fork but under judicious farm management, and the row culture, by the common plough.*

5939. *The coulter is removed and the plough goes first along one side of all the ridges of a ridge, or any convenient breadth and then, when the potatoes so brought to view are gathered by women placed at proper distances, it returns and goes along the other side. When the land is somewhat moist, or of a tenacious quality the furrow slice does not give out the roots freely and a harrow which follows the plough is commonly employed to break it and separate them from the mould. Various contrivances have been resorted to for this purpose. A circular harrow or break, of very recent invention, to be attached to the plough has been found to answer the purpose well, and to effect a considerable saving of labour. A machine for taking up and collecting potatoes is said to have been invented by Mr Michael Barry of Swords near Dublin but though we have written to that gentleman, we have been unable to procure a description or drawing of his invention.*

5940. *A mode of taking part of a crop suited to cottagers and others, especially in years of scarcity deserves to be mentioned. Having ascertained that some of the tubers have attained an edible size, up along the rows and loosen the earth about each plant with a blunt stick taking two or three of the largest tubers from each and returning the earth carefully. By keeping the edge of the blunt spatula or spade perpendicular to the main stem of the plant, the flat side will be parallel to the radiating roots, by which means they will be comparatively little injured. By this means both an early supply and the advantage of two or three crops are obtained. The tubers which remain will increase in size, having now the nourishment destined to complete the growth of those removed.*

5941. *Potatoes intended for seed should be taken up a fortnight or three weeks before being fully ripe, for reasons that have been given in treating of early potatoes, and will be resorted to in treating of the diseases of this plant. The ill shaped, small, bruised, or diseased tubers should be laid aside, and the fairest and best dried in the sun spread on a cellar or loft floor and covered with straw, or chaff of sufficient thickness to keep out the frost. In this state they may remain till wanted for sowing. Some persons in Ireland plant potatoes from which they intend to procure sets extremely late, namely the first week in July. The produce consequently never attains the same degree of size or ripeness as that of an earlier planted crop.*

5942. *Potatoes are stored and preserved in houses, cellars, pits, piers, and camps. Whatever mode is adopted, it is essential that the tubers be perfectly dry otherwise they are certain of rotting, and a few rotten potatoes will contaminate a whole mass.*

5943. *The most effectual mode and that which is generally adopted, consists in putting them into close houses and covering them well up with dry straw. In some parts of Scotland it is a common practice to dig pits in the potato field, when the soil is dry and light, and, putting in potatoes to the depth of three or four feet, to lay a little dry straw over them, and then cover them up with earth so deep that no frosts can affect them. Another method, which is practised in England as well as Scotland, is to put them together in heaps, and cover them up with straw in the manner of preserving turnips, with this addition that the heaps are afterwards well covered with earth and so closely packed together as to exclude frost. The farmers in Lancashire in the course of taking them up sort and separate their potatoes according to their uses, and are particularly careful to throw aside all those that are spotted before raising, or that are cut in the taking up. This is a very necessary and proper precaution (although by no means generally attended to) as the crop must have a much better chance for keeping, than when diseased or cut potatoes are stored up with it. It is also of great advantage to have the work performed in a dry season, as the potatoes seldom keep well when taken up wet, or when placed in any sort of repository for keeping whole in that state.*

5944. *Potato piers as they are called, are recommended by Young as the best mode in which potatoes can be stored. A trench one foot deep and six wide, is dug, and the earth cleanly shovelled out, and laid on one side, and on the bottom of the trench is laid over them a bedding of straw. One horse carts short down the potatoes into the trench and women pile them up about three feet high in the shape of a house roof. Straw is then carefully laid over them six or eight inches thick, and covered with earth a foot thick, neatly smoothed by flat strokes of the spade. In this method he never lost any by the severest frosts but in case of its freezing with uncommon severity another coat of straw over all gives absolute security. These pits when opened should each be quite cleared, or they are liable to degradation. I received one at a time, besides also being at first filled for immediate use he has a house that holds about 700 bushels, formed of posts from fir plantations with wattled sides against which is laid a layer of straw and against the sides exteriorly earth six feet thick at the bottom and eighteen inches at top, the roof flat, with a stack of beams upon it. Thus he has found frost-light. The beams keep out the weather he says, and yet admit any steam which rises from the roots which, if it did not escape, would rot them.*

5945. *Several other modes of preserving potatoes are in use in different places. In Rutlandshire, Marshall says, the method of laying up potatoes is universally that of camping them, a method somewhat similar to the above, but which requires to be described. Camps are shallow pits filled and ridged up as a roof with potatoes which are covered up with the excavated mould of the pit. This is a happy means he thinks, between burying them in deep pits and laying them upon the surface. Camps are of various sizes being too frequently made in a long square form like a earthenick and of a size proportioned to the quantity to be laid up. It has, however been found by experience, that when the quantity is large, they are liable to heat and spoil much damage having sometimes been sustained by this imprudence. Experienced campers hold that a camp should not be more than three feet wide four feet are perhaps as wide as it can be made with propriety proportioning the length to the quantity. If this is very large, forming a range of short ones by the side of each other. The usual depth is a foot. The bottom of the trench being bedded with dry straw the potatoes are deposited, ridging them up as in measuring them with a bushel. On each side of the roof long wheat straw is laid, neatly and evenly as thatch, and over this the mould raised out of the trench is evenly spread making the surface firm and smooth with the back of the spade. A coat of coal ashes is sometimes spread over the mould as a still better guard against frost. It is needless to observe that a camp should have a dry situation, and the roots ought to be deposited in as dry a state as possible. These camps are tamped at the end, some by hand, or a quantity of loose straw being thrust down in the open end, as a bung or safeguard. As it is a matter of the highest importance to preserve this root without spoiling during the whole year it has been suggested, that the best method yet discovered for keeping potatoes sound for the longest period, is to spread them on a dry floor early in the spring, and to rub off the eyes occasionally as they appear to have a tendency to push out by using these precautions, Donaldson has frequently seen potatoes kept in good condition till the month of June.*

5946. *In Canada and Russia the potato is preserved in boxes in houses or cellars, heated when necessary to a temperature one or two degrees above the freezing point by stoves. (Farm Mag vol. xx p. 446.)*

5342. To keep potatoes any length of time, the most effectual way is to place them in thin layers on a platform suspended in an open air. There the temperature being always below that of active vegetation, they will not sprout; while not being above one or two degrees below the freezing point, the tubers will not be frost bitten. Another mode is to scald out the eyes with a very small scald, and keep the roots buried in earth. A third mode is to destroy the vital principle by kiln-drying, steaming, or roasting. A fourth mode is to bury them in dry soil that no change of temperature will reach them, and consequently being without air, they will remain upwards of a year without vegetating.

5343. The produce of the potato varies from five to eight, and sometimes ten or twelve tons per acre: the greatest produce is from the yam, which has been known to produce twelve tons or 480 bushels per acre. The haulm is of no use but as manure, and is sometimes burned for that purpose, being slow of rotting.

5344. The most important application of the potato crop is as human food: on this it is unnecessary to enlarge.

5350. *Blanch's* French potato contains twenty-four per cent. of their weight of nutritive matter and six and a half measures of potatoes afford the same nourishment as twenty-four measures of rye. A thousand parts of potato yielded to Sir H. Davy from 900 to 860 parts of nutritive matter, of which from 166 to 800 were mucilage or starch fifteen to twenty sugar and thirty to forty gluten. Now supposing an acre of potatoes to weigh nine tons, and one of wheat one ton, which is about the usual proportion; then as 1000 parts of wheat afford 850 nutritive parts, and 1000 of potato say 860, the quantity of nutritive matter afforded by an acre of wheat and potatoes will be nearly as nine to four; so that an acre of potatoes will supply more than double the quantity of human food afforded by an acre of wheat. The potato is perhaps the only root grown in Britain which may be eaten every day in the year without offending the palate, and the same thing can only be said of the West India yam and bread fruit. They are, therefore, the only substitutes that can be used for bread with any degree of success and indeed they often enter largely into the composition of the best loaf bread without at all injuring either its nutritive qualities or flavour. (*Edin. Encyc. art. Baking.*) In the sower by Dr Tineot to M. Languet, the farmer objects to the constant use of potatoes as food, not because they are pernicious to the body, but because they hurt the faculties of the mind. He owns that those who eat maize, potatoes, or even millet, may grow tall and acquire a large size but doubts if any such ever produced a literary work of merit. It does not, however, by any means appear that the very general use of potatoes in our own country has at all impaired either the health of body or vigour of mind of its inhabitants.

5351. The manufacture of potato flour is carried on to a considerable extent in the neighbourhood of Paris, and the flour is sold at a price considerably higher than that of wheat, for the use of confectioners and for bakers who prepare the finest sorts of bread. The potatoes are washed and grated, and the starch separated from the pulp so obtained by filtration. It is dried on shelves in a room heated by a fire, and afterwards broken up on a floor by passing a cast iron roller over it. It is then passed through a bolting machine and put up in sacks for sale. The most complete manufactory in the neighbourhood of Paris in 1829 was that of M. Delisle at Bondy (*Gard. Mag. vol. vi.*) Most of the operations there are performed by a steam engine attended by children. It is reported by the Count de Chabrol, in his *Statistical Account of Paris*, that 40,000 tons of potatoes are annually manufactured into flour within a circle of eight leagues around this city.

5352. The quantity of farina which potatoes produce varies not only according to the species, but according to the position when the extraction takes place. The variations produced by this last cause are nearly as follows:—Two hundred and thirty pounds of potatoes produce of farina, or potato flour in

August, from 23 to 25 pounds.	March from 45 to 28 pounds.
Sept..... 32 ... 35	April .... 32 ... 35
Oct..... 32 ... 40	May..... 28 ... 30
Nov..... 32 ... 45	

The extraction of the farina should be discontinued at the period when the potatoes begin to grow the farina being destroyed by germination. Red potatoes produce a smaller quantity of farina. These which are blue on the outside give little, but it is of good quality: the white, which is often tinged with red in the interior is the best proper for this extraction. The best of all is that which has a yellow tint, as its farina is of very good quality, and abundant. (*Diag. de Bruxelles.*)

5353. *Potato flour* is made into bread in a very simple manner. Its adhesive tendency does not admit of baking or kneading mixed with meal or wheaten flour: but it may be made into cakes in the following manner. —A small wooden frame nearly square is laid on a flat pan like a frying-pan; this frame is grooved, and so constructed, that, by means of a presser or lid introduced into the groove, the cake is at once fashioned according to the dimensions of the mould. The frame containing the farina may be almost immediately withdrawn after the mould is formed upon the pan; because, from the consistency imparted to the incipient cake by the heat, it will readily admit of being safely handled. It must not, however, be dried too hastily: otherwise it is apt to become unpleasantly hard and unfit for mastication. This precautionary measure being observed, it will be found that, where thoroughly ready the bread of potato flour even mixed by any foreign ingredient, will eat very palatably. It might thus from time to time, be soaked for puddings, like the tapioca; or it might be used like the cascade cake, which in appearance and quality it so much resembles; that is, when well buttered and toasted, it will make an excellent breakfast appendage. (*Gard. Journ. Agr. vol. ii. p. 63.*)

5354. The meal of potatoes may be preserved for years closely packed in barrels, or unground in the form of slices; these slices having been previously cooked or dried by steam, as originally suggested by Koryth of Edinburgh. (*Encyc. Brit.*) Some German philosophers have also proposed to freeze the potato, by which the acrid matter is separated from the starch, and the latter being then dried and compressed, may be preserved for any length of time, or exported with ease to any distance. (*Annalen des Naturforsch., vol. iii. p. 329.*)

5355. The manufacture of *Isinglass* from potatoes is thus given in the *Quarterly Journal of Agriculture*. The potatoes selected are thoroughly washed, after which they are grated in a machine constructed for the purpose. The parts thus reduced or grated fall into a vessel placed underneath. From this vessel they are removed, and drained into a tub. On the juice being well expressed for the first time, the fibrous matter is cut small, and cold clean water is thrown over them. These fibres are again put through the same strainer. All the waste of the substance is collected, when they are finally cut small. On this being done, the contents of the tub, now in a state of masticity or slush, are allowed to settle. A reasonable interval being suffered to elapse, the old water is poured gently off, and fresh water supplied. After this process of draining and washing, the blanched matter is passed through a smaller strainer.

5356. The *skins are separated*. The starch becomes now much whiter; still fresh water is abundantly added over it. When by frequent addition the surface of this vegetable mass is rendered quite smooth and level it is strained a third and last time.

5357. The *strainer now used* is of very fine texture, so that no improper or accidental admixture may intervene. As soon as the starch, thus purified, has firmly subsided, it is spread on a board, and exposed to the open air. The damp quickly evaporates, on which it is, as a security for cleanliness, put through a sieve.

5359. A large circular pan is now procured, and set upon the fire. The fire is gradually put into the pan, till what is conceived to be sufficient for one cooking be supplied. As the natural tendency of the farina, in a warm state, is to adhere to the pan, great care is requisite in constantly turning and stirring it. This is effectually done with a broad flat piece of wood, having a long handle to prevent inconvenience from the heat. A temperature of 150° Fahrenheit suits best for perfecting the lapioca. When the farina becomes quite hard, dry and gritty, it is then ready and may be taken off the fire. (*Quek. Journ. Agr.* vol. II, p. 85.)

5359. The ordinary economical applications of the potato, next to those of the culinary and baking arts, are in starch-making and the distillery. Starch is readily made from the scraped and washed tubers cut into small pieces and steeped in water and a spirit is distilled from mashed potatoes, fermented so as to change a portion of the starch into sugar. In general it is found that three and a half bushels of potatoes afford the same quantity of spirit as one of malt.

\*5360 Potash may be extracted from potato leaves and stalks by the following process. — Cut off the stalks when the flowers begin to fall as that is the period of their greatest vigour; leave them on the ground eight or ten days to dry, cart them to a hole dug in the earth about five feet square and two feet deep, and then burn them keeping the ashes red-hot as long as possible. Afterwards take out the ashes, pour boiling water on them, and then evaporate the water. There remains after the evaporation a dry saline reddish substance, known in commerce under the name of *ashes*, the more the ashes are boiled, the grayer and the more valuable the *ashes* become. The *ashes* must be calcined in a very hot oven, until the whole mass presents a uniform reddish brown. In cooling it remains dry and in fragments bluish within and white on the surface; in which state it takes the name of *potash*. (*Swedia. & Mecklen.* vol. II, p. 381.)

5361 Among extraordinary applications of the potato, may be mentioned cleaning woollens, and making wine and ardent spirit.

5362. *Cleaning woollens.* The refuse of potatoes used in making starch when taken from the sieve, possesses the property of cleansing woollen cloths, without hurting their colour, and the water decanted from the starch powder is excellent for cleansing silks without the smallest injury to the colour.

\*5363. *Wine* of a good quality may be made from frosted potatoes if not so much frosted as to have become soft and watery. The potatoes must be crushed or bruised with a mallet, or put into a cider press. A bushel must have ten gallons of water, prepared by boiling it, mixed with half a pound of hops, and half a pound of common white ginger. This water, after having boiled for about half an hour must be poured upon the bruised potatoes, into a tub or vessel suited to the quantity to be made. After standing in this mixed state for three days, yeast must be added to ferment the liquor. When the fermentation has subsided the liquor must be drawn off as fine as possible into a cask adding half a pound of raw sugar for every gallon. After it has remained in the cask for three months, it will be ready for use.

\*5364. *Ardent spirit.* Potatoes that have been injured by the frost produce a much greater quantity of spirit, and of a much finer quality than those that are fresh; they require a proportion of malt-wash to promote the fermentation. About one fourth part of malt-wash or wash ought to be fermented at least six hours before the potato-wash is joined to it; otherwise the potato-wash, having an aptitude to ferment, will be ripe for the still before the malt-wash is ready; hence the effect will be, to generate an acid which renders the spirit coarse, and when diluted with water, of a milky or bluish colour. When the spirit is strong, the acid is held in solution but appears as above, when diluted with water. (*Farmers & Mag.* vol. XVII, p. 323.)

\*5365. In the application of potatoes as food for live stock they are often joined with hay straw chaff and other similar matters, and have been found useful in many cases, especially in the later winter months, as food for horses, cows, and other sorts of live stock. With these substances, and in combination with others, as bean or barley meal and pol lard, they are used in the fattening of neat cattle, sheep and hogs.

5365. Potatoes are much more nutritive when boiled; they were formerly cooked in this way but are now very generally steamed, especially in the north. The practice has been carried to the greatest extent by Curwen in feeding horses. He gives to each horse, daily a stone and a half of potatoes mixed with a tenth of cut straw. One hundred and twenty stones of potatoes require two and a quarter bushels of coals to steam them. An acre of potatoes, he considers goes as far in this way as four of hay. Von Thuer found them, when given to live stock, produce more manure than any other food. 100 lbs of potatoes producing 65 lbs. of manure of the very best description. The baking of potatoes in an oven has also been tried with success. (*Comm. Board of Agriculture* vol. IV. but the process seems too expensive. Potatoes should not be given raw to animals of any description, except, perhaps, when hogs are let in to root and pick up what may have escaped notice in the field. Washing was formerly a disagreeable and tedious business but is now rendered an easy matter whether on a large or small scale, by the use of the washing machine.

5367. *Machines for washing potatoes* are numerous, and in addition to that already described, we shall here notice two other forms. One of the simplest is a trough (Fig. 750, a, b) containing a hollow cylinder

off by another hook at the opposite end. (*Brit. Farm. Mag.* vol. IV.)

5368. The *baking of potatoes*, though a simple operation, is in many districts not performed in the best manner. The following is the Lancashire method. — Set them on the fire in cold water, when boiled, pour off the water completely add a little salt, and dry them well on the fire. Another method: — Choose your potatoes of equal size, and put them into a saucepan, or pot without a lid, with no more water than is sufficient to cover them; more would only spoil them, as the potatoes themselves, on being boiled, yield a considerable portion of water. By being boiled in a vessel without a lid, they do not crack, and all waste

(c) with a handle (d) which is made fast to the axis which passes through the cylinder. A number of the spars (which run longitudinally) are so constructed as to form a kind of door which is made fast by two 1/2 inch pins at each end of the cylinder. The vessel being charged with potatoes, and the trough filled with water all that is necessary for the purpose of cleaning is only to turn the handle of the machine. A machine for washing potatoes by Mr. John Lawson, of Elgin, consists of a wooden or iron trough, with a movable bottom above the fixed one composed of spars three quarters of an inch apart. The potatoes are laid over the movable ribbed bottom, and water being admitted at one end and by a cock they are moved backwards and forwards by a wooden hoe, till they are clean, when the dirty water which has collected between the two bottoms is let

is prevented. After the water is quite ready to boil, pour it off, and replace the hot by cold water into which throw a good portion of salt. The cold water sends the heat from the surface to the heart of the potato, and makes it mealy. Like all other vegetables, they are improved by being boiled with salt, which ought not, therefore, to be spared. (*Mod. Mag.* 1. 13.)

5369. *Frosted potatoes* may be applied to various useful purposes, for food by thawing in cold water, or being parod, then thawed, and boiled with a little salt. Salt, or salt-petre, shell, or bruised oats, boiled with them, will render them fit food for cattle, swine, poultry, &c. Starch, and paste for weavers, bookbinders, and shoemakers, may be made from them when too sweet to be rendered palatable, and also an ardent spirit, from hydrometer proof to 10 per cent over proof.

5370. *The diseases of the potato* are chiefly the scab, the worm, and curl.

5371. *The scab, or mottored surface of the tubers*, has never been satisfactorily accounted for; some attributing it to the memento of horn-dung, others to alkali, and some to the use of coal ashes. Change of seed, and of ground, are the only resources known at present for this malady. The worm and grub both attack the tuber and the same preventive is recommended. The only serious disease of the potato is the curl, and this is now ascertained to be produced by the too great concentration of the sap in the tuber; and this concentration, or thickening, is prevented by early taking up. The discovery was first made by the farmers near Edinburgh, who observed that seed potatoes procured from the moors, or elevated cold ground, in the internal parts of the country never suffered from the curl, and it consequently became a practice, every three or four years, to procure a change of seed from those districts. On enquiry, it was found, that the potatoes in these upland grounds continued in a growing state till the autumn was blackened by the first frosts of October. They were then taken up, when, of course, they could not be ripe. Subsequent experiments, which will be found detailed in *The Farmer's Magazine* and *Chesham and London Horticultural Transactions*, have firmly established the fact, that the curl is prevented by using untimely seed: therefore the farmer ought to select his seed stock a fortnight or three weeks before he takes up the general crop, as already recommended. It is also a safe practice frequently to change the seed, and also to change the variety.

5372. *Shrivell*, an insidious and practical agriculturist, is of opinion that there are only two causes for the curled disorder in potatoes. The first is excessive seed-bearing, that is, carrying great quantities of plums or apples from the effects of which, if the plant be not too far advanced in life, it may recover for a time, by removing it to a shady or upland situation. The second cause is time or old age, which never fails ultimately to bring the curled or shrivelled disorder followed by death on the whole animal and vegetable kingdoms. An old decaying oak is an instance of the curled or shrivelled state of trees from age, as is "the lean and shaggy pantaloon" of the curled disorder from old age in the human species. An apple tree, again, that has borne extraordinary crops of fruit within a few years is often in the state of a potato curled from excessive apple-bearing: so is a hart, or a buck, immediately after the rutting season. Both the tree and animal will recover their health and vigour for a time unless they are too old, or have gone to the very greatest and last extremity in seed-bearing and ventury, in which cases the effects will be the same as those of time, viz. death. It is not then to over ripening the tubers that the curled disorder in potatoes is to be attributed, but to time and seed-bearing: that is, carrying great quantities of plums or apples.

SECT. II. *The Turnep*. — *Brassica Rapa* L. *Tetradymia Stiquida* L. and *Crucifera* J. *Rosa*, Fr.; *Rabe*, Ger. *Rapa*, Ital. and *Nabo*, Span.

5373. *The turnep* is a native of Britain, but in its wild state it is not to be recognised by ordinary observers from wild mustard. It was cultivated as food for cattle by the Romans and has been sown for the same purpose in the fields of Germany and the Low Countries from time immemorial.

5374. *When they were introduced in the country as a field plant*, is unknown but it is probable turneps would be found in some gardens of convents from the time of the Romans and it is certain that they were in field culture before the middle of the seventeenth century though then, and for a long time after wards, in a very inferior and ineffectual manner. It has been stated that turneps were introduced from Hanover in George I.'s time, but so far from this having been the case, George II. caused an abstract of the Norfolk system of turnip husbandry to be drawn up for the use of his subjects in Hanover (*Campbell's Polit. Survey* see vol. iii. p. 80). The introduction of improved turnip culture into the husbandry of Britain, Brown observes, "occasioned one of those revolutions in rural art which are constantly occurring among husbandmen and, though the revolution came on with slow and gradual steps, yet it may now be viewed as completely and thoroughly established. Before the introduction of this root, it was impossible to cultivate light soils successfully or to devise suitable rotations for cropping them with advantage. It was likewise a difficult task to support live-stock through the winter and spring months and as for feeding and preparing cattle and sheep for market during these inclement seasons the practice was hardly thought of, and still more rarely attempted, unless where a full stock of hay was provided, which only happened in very few instances. The benefits derived from turnip husbandry are therefore, of great magnitude. Light soils are now cultivated with profit and facility, abundance of food is provided for man and beast, the earth is turned to the use for which it is physically calculated and, by being suitably cleared with this preparatory crop, a bed is provided for grass seeds, wherein they flourish and prosper with greater vigour than after any other preparation" (*Treatise on Rural Affairs*).

5375. *Turnips and clover*, it is elsewhere observed, "are the two main pillars of the best courses of British husbandry; they have contributed more to preserve and augment the fertility of the soil for producing grain, to enlarge and improve our breeds of cattle and sheep, and to afford a regular supply of butcher's meat all the year than any other crops, and they will probably be long found vastly superior, for extensive cultivation, to any of the rivals which have often been opposed to them in particular situations. Though turnips were long cultivated in Norfolk before they were known in the northern counties, yet it is an undoubted fact that their culture was first brought to perfection in Roxburghshire, Berwickshire, and Northumberland, and chiefly through the exertions of Dawson, of Froghda, in the first named county, and of Cullay in the latter.

5376. *Drilling turnips*, as well as other crops, evidently originated with Tull, whose first work, *Specimens of a Horse-Drilling Husbandry*, appeared in 1721. It appears that Crompton, of Arburyland, in Dumfriesshire, began to drill turnips about 1744, and next year John Philip Howard, of Cooch, drilled in 1745; and Fringle, *drilling* "from hints taken from Tull's book," in 1756 or 1757. William Dawson, who was well acquainted with the turnip culture in England, having been purposely sent to reside in those districts

for six or seven years, where the best cultivation was pursued, with an intention not only of saving, but of seeking himself master of, the manual operations, and of the miracle in the practice, was convinced of the superiority of Fringle's mode over every other he had seen, either in Norfolk or elsewhere; and in 1762, when he entered on Frogmore Farm, near Kew, in Kent, he immediately adopted the practice upon a large scale to the amount of 100 acres yearly. Though none of Fringle's neighbours followed this example, yet no other did Dawson, an actual or rent-paying farmer adopt the same system, than it was immediately followed, not only by several farmers in his vicinity but by those very farmers adjoining Fringle, whose crops they had seen, six or twelve years, so much superior to their own the practice in a few years became general. Drilling turnips was first introduced to the county of Northumberland, about the year 1780.

5377 *The varieties of turnip grown by farmers may be arranged as whites and yellows.*

5378 *Of white turnips* by far the best and most generally cultivated is the globe but there are also the green-topped, having the bulb tinged greenish and purple-topped with the bulb reddish which though they do not produce so large a crop as the globe or oval stand the winter better and the red-topped it is said, will keep till February. The pudding, or tankard turnip, has a white bulb which rises from eight to twelve inches high, standing almost wholly above ground. It is less prolific than any of the others, and more liable to be attacked by frost.

5379 *Of yellow turnips* there are the field or Aberdeen yellow which is more hardy than the globe, and answers well for succeeding that variety in spring and the rutabaga, or Swedish turnip, which may be preserved for consumption till June. The Siberian turnip has a bulb and a branchy top, but both of inferior quality. It is a hybrid between a white rutabaga and field cabbage, or between rape and cabbage.

5380 *New varieties* are obtained by selection and by counter impregnation, but in either case the greatest care is requisite to keep the plants at least a furlong from any others of the same tribe likely to flower at the same time otherwise the progeny will certainly be hybridised.

5381. *The choice of sorts* may be considered as limited to the white, globe yellow, and Swedish according as early mudding, or late supplies are wanted. No other varieties are grown by the best farmers.

5382. *In the choice of seed* the farmer must rely on the integrity of the seed-dealer as it is impossible to discover from the grains whether they will turn out true to their kind.

5383. *Turnip-seed requires to be frequently changed* and the best is generally procured from Norfolk and Northumberland. The Norfolk seed Longth observes is sent to most parts of the kingdom, and even to Ireland but after two years it degenerates so that those who wish to have turnips in perfection should procure it fresh every year from Norwich and they will find their account in so doing for from its known reputation, many of the London seedsmen sell, under that character seed raised in the vicinity of the metropolis, which is much inferior in quality.

5384. *Turnip-seed of any age will grow* if it has been carefully preserved that which is new comes up first, and therefore it is not a bad plan to mix new and old together as a means of securing a harvest against drought or the fly. Whether plants from new or old seed are most secure from the depredations of the fly is perhaps a question which cannot be easily determined, even by experiments, for concomitant circumstances are frequently so much more operative and powerful as to render the difference between them if there be any, imperceptible. It is, however known to every practical man that new seed vegetates several days before the old, and more vigorously and it is equally well known that the healthy and vigorous plants escape the fly when the stunted and sickly seldom or never escape it. Hence it would seem that new seed, *castore paribus* is more secure from the fly than old.

5385. *The soil* for turnips should always be of a light description. In favourable seasons very good crops may be raised on any soil but from the difficulty of removing them and the injury which the soil must sustain either in that operation or in eating them on the spot with sheep, they never on such soils can be considered as beneficial to the farmer. Turnips cannot be advantageously cultivated on wet tenacious soils, but are grown on all comparatively dry soils under all the variations of our climate. On dry loams, and all soils of a looser texture, managed according to the best courses of cropping, they enter into the rotation to the extent of a fourth, a sixth or an eighth part of the land in tillage and even on clayey soils they are frequently cultivated, though on a smaller scale, to be eaten by cattle, for the purpose of augmenting and enriching the manure, into which the straw of corn is converted.

5386 *The climate* most desirable for the turnip is cool and temperate. This was long ago noticed by Pliny, and it is so obvious on the Continent that it admits of no dispute. Von Thier observes that the turnips grown on the fields of Germany seldom exceed half a pound in weight, and that all his care could not raise one beyond fourteen pounds. In France and Italy they are still less. A rapid climate is equally disadvantageous to the turnip and they are accordingly found of no use in Russia, Sweden and many parts of North America. Even turnips grown in the southern counties of England, in the same excellent manner as in Northumberland, never equal the size of those grown in the latter county, or further north, or in Ireland.

5387 *The field culture of turnips* is effected either by sowing the seed of the plant from the hand on a flat surface or by depositing it on the tops of little ridges. In the best cultivated districts, the latter method is universally practised and approved of, chiefly for these reasons — 1 By this method the land may be more easily and perfectly cleaned during the growth of the plants the width of the rows affording the means of better tilling the intervals. 2 The plants can be more cheaply and quickly hand-hoeed, the process being so simple as to be taught to young persons in a few hours whereas when the plants are not regularly disposed in rows, a considerable degree of experience and time are requisite. 3. The manure may be more perfectly covered, and by being applied in a more effectual manner to the roots of the plants, a smaller quantity will suffice. And lastly, the turnips may be kept drier, and crops of them in conse-

which intend on land as wet as subsoils to be incapable of yielding a return of any value. We shall give their culture from an excellent paper in the *Quarterly Journal of Agriculture*, vol. 1, from which also this paragraph is quoted.

**589. Preparation of the land.** The land intended for the turnip crop is ploughed in autumn, after the preceding crop of grain has been reaped. If the soil be not of a very dry nature, the land is formed into ridges of three feet or more, and care is taken that no water shall stagnate on the ground. In this condition the land remains during the winter, and it is ploughed again in spring as soon as the ground is sufficiently dry for that purpose, and as soon as the other labour of the farm will allow. This second ploughing is generally made in a direction to cross the previous one. The land is then repeatedly grubbed and harrowed in various directions, for the purpose of pulverising it, and of dragging to the surface, and decomposing all weeds and roots to assist in which process the aid of the roller is frequently requisite, the roots and weeds decomposed are then gathered with care and either burnt in little heaps on the ground, or removed away to a larger heap, to be mixed with quack lime and other substances, to form a compost for the succeeding year. At the same time such stones as impede the tillage may be removed. After this the land is again ploughed, and generally as before, in a direction crossing the last furrows, and the same process of harrowing, rolling, and collecting the decomposed weeds, is repeated. The earth is once more ploughed, and again the same operations are resorted to, after which the land is usually in a fit state to be sown in ridges or drills. Should this not be so, the operations of ploughing, harrowing, and gathering of weeds must be repeated, and that until the land is cleared of all injurious roots, and reduced to a loose or friable state. The perfect preparation of the ground in this stage of its culture is of very great importance to the future crop.

**590. Forming the ridges.** After the preparation described, the land is formed into little ridges or ridgelets, either by the common plough, or by a plough with two mould-boards, formed for that purpose. The first of these is to be preferred when the method of performing the work is once pointed out in this field. The ridges are formed with a sharp top, as a transverse section (fig 751.) will show. The distance

751

of these ridgelets may be from twenty-seven to thirty inches, measuring from top to top. This interval is necessary to allow of the horse hoe filling the intervals, in the manner to be afterwards described, and to admit a sufficient circulation of air between the rows of the plants.

**590. Manner of applying the manure.** The chief manure applied to this crop is farmyard dung, or that which is produced by the consumption of the straw and other produce of the farm. This manure ought to be well rotted, and to that end either turned over in the court-yard some weeks previously to its being used, or carried on in winter to the fields intended for the turnips, and there laid in one or more large heaps. If the carts are not suffered to go upon these heaps, the putrefactive process will proceed with greater quickness. When the ridgelets are formed in the manner described, the dung is filled into carts drawn by one horse, and transported quickly to the land. The manner of applying it is this — The horse with the loaded cart walks in the interval of the ridges, so that a wheel of the cart shall go in each of the hollows of the two ridges adjoining. The person who directs the horse follows the cart, which is open behind, and with a crooked two-pronged fork or dung hook (fig 752.) drags out the dung, as the horse moves along, into little heaps in the hollow of every third ridge, at the distance from each other of from eight to ten feet. Be-

752

hind follow three young persons, with each a two pronged or three-pronged fork (fig 753.), each walking in the interval of a ridge, and spreading out the dung in as regular a manner as possible as a cross section of the ridgelets with the dung deposited in the intervals would show (fig 754.)

753

**591. Covering the dung.** The dung is no sooner spread in this manner than it is covered by the plough. To this end is employed either the common plough or that with the double mould board already mentioned these passing down the middle of each ridgelet split it into two, so that a new ridgelet is formed, whose top is immediately above the former hollow of the old ridgelet. (fig 755.) The dung is now completely covered, and a new ridge for the reception of the seed is at once formed. The double mould board plough performs this

754

operation at once, the common plough by going and returning up the middle of each ridge.

755

**592. Broad-sown sowing.** Instead of depositing the manure in the manner described, it is sometimes laid upon the stubble after harvest, and then ploughed in. This is only practicable where there is a supply of manure remaining from the preceding year, or where it can be elsewhere procured, and is only ad- visable when the land is so clean as to require little preparation in the succeeding spring. As liberal an expenditure as can be afforded of manure is always expedient in the case of this crop, the goodness of which will much depend upon the fertility we are able to communicate to the soil. Ten or twelve tons per acre may be considered the regular manuring on a turnip-farm, where a proper rotation of crops is followed.

**593. Lime, sea-sand, &c.** Sometimes lime is applied to the turnip crop, together with dung. This may be done by laying the lime upon the stubble after harvest, or before sowing, by spreading it upon the ground, and harrowing it well immediately before the sowing of the ridgelets for the reception of the seed. Putrefactive manures, however, are considered superior to the calcareous for the production of this plant, and all of the former kind may be used with effect. Street dung is an exceedingly good manure, sea-sand will also be useful; this last, however, is not applied in the manner of the farmyard dung, but is carried off so it is met on shore, laid on the surface, and suffered to remain so till the land is

ploughed. *After* generally produces a good effect in causing the seeds to vegetate quickly, but the fertilizing power of some of these do not appear to be of a permanent nature. In almost every and various other experiments have been used with much benefit; but it is to be observed, that permanent manures form the main support of the turnip culture, and that the others are only to be regarded as subsidiary.

5394. *Sowing the turnips* The land being formed into ridgelines in the manner described, is ready for the reception of the seed. This is sown on the tops of the ridgelines by machines of various forms.

5395. *The most simple of these* consists of a hollow cylinder of tin, fixed upon an axle, and moving round with two light wheels, distant from each other twenty-seven or thirty inches, which are made to run in the hollows of the ridges. (Fig. 756.) The seed is put into the cylinder through an aperture which opens and shuts for that purpose this cylinder turning round with the axle, the seed drops, through small equidistant holes made in it, into a tin tube, by which it is conveyed to the ground. Immediately before this tube is a hollow coulters of iron, sharp before, which incloses the forepart of the tin tube, and makes a track in the ground from one to two inches deep, into which the seed drops. This simple apparatus is mounted upon a light wooden frame-work, having two shafts behind, by which the workman holds and keeps it steady in its course. It is then attached by a rope to a light wooden roller, in the shafts of which the animal of draught is yoked. More perfect machines, however, may be employed where turnips are cultivated upon a large scale, and we may refer to that of French (Fig. 756.) as one of the best.

5396. *The preparation of turnip-seed for sowing* by steeping in the drainings of dung-hills and other similar matters, has been recommended as a likely mode to prevent the fly but it is not found to have this effect, and is never followed.

5397. *The following mode of preparation is sometimes adopted*—Half new and half old seed are mixed together, then half is taken and steeped in water for three or four hours afterwards both steeped and unsteeped seed are mixed and immediately sown. The object of this preparation is to obtain four different brands or rungs of the seed which are supposed to give four chances of escaping the fly that attacks the infant plants, instead of one. Another mode is to join radish seed to the above, new and old steeped in the foregoing manner, it being found that the fly prefers the radish to the turnip. Some recommend the mixing of an equal quantity of rape-seed with the turnip-seed, alleging that if a fly cuts off the turnip, the rape may be left for a crop and that if the turnip escapes, the rape may be treated as waste. The most common precaution, however as to the fly is to sow thick, or to mix the seed with soot, lime, or ashes.

5398. *The quantity of seed used* may be from two pounds to two and a half pounds avoirdupoise per acre. It is necessary to give a sufficient quantity of seed, to provide against the loss of plants from the ravages of insects, and other contingencies. But the quantity should not be excessive because the plants, when too thick get interwoven together, and thence become difficult to be thinned in a proper manner.

5399. *The sowing process being completed*, the ridgelines remain flattened and compressed. (Fig. 756.)

756

5400. *The several operations of forming the ridgelines, spreading the dung, conveying it by the plough, and sowing the seed, ought to be carried on in close succession* The dung must be immediately covered, that none of its powers may be lost by evaporation and the seed to ensure its early vegetation, ought to be sown as soon as possible upon the moist earth turned up. The various works of the turnip culture, thus carried on at the same time, furnish the best specimen which the culture of the fields affords of the beneficial effects of a proper division of labour. The process has all the appearance and effects of garden culture, with the difference of its being conducted with incomparably greater economy and despatch.

5401. *The period of sowing* in the north of England and Scotland is from the 1st to the end of June, though it is often continued to the middle of July. The turnips, however sown after the latter of these periods seldom attain to a proper size and, when sown earlier than the 1st of June, they are apt to shoot forth the seed-stem before winter, by which not only the soil is deteriorated, but the nutritive juices of the root exhausted. In the south of England they may be sown somewhat later than in the north.

5402. *The time of sowing in other countries* must be varied by the nature of the climate and soil. It is to be inferred, that in warmer countries, where vegetation is more rapid, the sowing should be deferred till a later period. At Bouville, in the north of France, M. de Dombasle sometimes sows in August, and yet obtains a medium crop.

5403. *Hoeing* When the plants are an inch or more in height, or when weeds appear amongst them, the process of hoeing commences. This is done either by a small plough drawn by one horse, going and returning along the hollow of each ridgelet, and cutting of a shoe of earth from the sides, as near to the turnips as possible (Fig. 757)

757

or by the horse-hoe, of which there are various kinds. The most simple of these consists of a flat triangular share (Fig. 758. a), with two lateral arms (b, b), formed to set wider or narrower, and fixed to a beam and handles by three upright coulters of iron set, which is better, the lateral arms are omitted, the triangular share fixed to the beam, and two moveable upright coulters attached by a cross bar.

## A METHOD OF A HORSE-HOE

758. One of the first horse-hoes is indicated from the skeleton of a common plough, *fig. 758*.

two handles of iron curved inwards (*a, b*), and fixed to wooden bars (*e, f* and *c, d*), which last again are hooked to the beams of the implement, and made, by means of a cross iron bar (*g, h*) to be set at a greater or smaller distance from each other as it may be required. A broad iron share (*i*) moves in the middle of the hollow of the ridges, while the two coulter on each side go as near to the rows of turnips as can be done with safety and in this manner the intervals of the ridges are tilled, and the weeds within them, and as near to the plants as the coulter can go, cut up and destroyed. By removing the wooden bar and coulter of this machine, and hooking to it, on each side, a small cast-iron mould-board, it is converted to the double mould-board plough also, as we have seen.

5405. The *brakes or horse-hoes* of WILKIN (1860a), FINLAYSON (1867), or of KIRKWOOD (1868), may easily be set and arranged for this or any other description of culture so that it requires no new implements.

5406. The *hand-hoes* go to work, each having a little iron hoe, fixed upon a wooden handle about three feet in length (*fig. 760*). The breadth of the blade (*a*) of this hoe is eight inches and the workers, standing in the hollow with their faces to the ridges, hoe the turnip plants, leaving them standing singly at the distance from each other of seven rows of the turnips are cleared of all weeds the superfluous plants cut up and pushed into the intervals, where they die and the plants to be preserved left standing singly at the distance required. A transverse section of the ridges will then appear thus (*fig. 761*) and

a longitudinal section thus (*fig. 762*). The plants should not be nearer to each other than ten inches, that they may increase to a proper size.

5407. *Second horse-hoeing*. Soon after the operation in question, weeds will again sprout up in the intervals of the ridges and amongst the plants. In the course, therefore, of twelve days or more the horse-hoe again passes through the intervals of the ridges, cutting up all the weeds that may have sprung up and soon after the hand-hoes again go to work with the same instrument as before cutting up all weeds which may have grown amongst the turnips, and carefully singling any plants that may by chance have been omitted in the first hoeing. After this process, a section of the ridges will appear thus (*fig. 763*)

5408. *Third horse-hoeing*. Sometimes the horse-hoe passes once more down the intervals after a short period; but more generally the previous hand hoeing concludes the process upon all the drier lands, the weeds being now kept down by the rapid growth of the plant, and the overhanging of the intervals by its leaves. Very commonly however at an interval of eight or ten days after the last hand or horse-hoeing, the earth which had been taken from the roots of the plants by these several hoeings is again laid back, either by the little one-horse plough already mentioned, or by the double mould-board plough, passing down the intervals of the rows and raising up the earth thus (*fig. 764*). The design in this operation is, that any weeds remaining in the intervals after the former hoeings may be destroyed, and that the hand sown turnips may be kept more dry during wet weather and the months of winter. This concludes the culture of the turnip, which now grows rapidly without further care, and by the beginning of September the leaves of a good crop will have covered the entire surface, making a transverse section of the ridges appear thus (*fig. 765*).

5409. The *Swedish turnip* is cultivated, used, and stored precisely in the same manner as the common turnip; but it is generally sown several weeks earlier. It does not attain to the same weight by the acre; and, as it is more difficult to raise, it ought to receive a greater quantity of manure, and to be always upon good land. The Swedish has a property which the common turnip has not, that of bearing to be transplanted

when young; so that, where blunks appear in a field, the spaces may be filled up by transplanting. Analogous to the Swedish turnip, in hardness and nutritive qualities, is the large yellow or Aberdeen turnip. This root is perhaps superior to the Swedish turnip, in so far as it may be raised with less difficulty. It serves the same purpose of a succedaneum to the common turnip in spring.

<sup>5410.</sup> *Consumption of the turnips.* By the end of October or beginning of November, when the pastures have decayed, the turnips begin to be used for food.

<sup>5411.</sup> *When sheep are to be fed, the turnips are either pulled up by the hand, and carried away as wanted, into the fields in which the sheep are kept, and there spread regularly upon the ground; or more frequently and economically the sheep are at once driven into the fields of turnips, and suffered to consume the roots as they stand. In this case the animals are not suffered to range over the whole field at first, but are confined to a space of an acre or more, by means of nets, or a series of moveable rails or hurdles. When the sheep have eaten the roots very nearly, the remainder in the ground may be picked up by a little hoe (fig. 764.) or by the turnip chopper already described (5372.) and when the whole are consumed, the nets or rails, or hurdles, are moved to another division, and so on throughout the field, leaving the spaces before cleared open to the sheep to move upon. This manner of consuming the turnips affords an admirable manure to the land, and preserves it well for the subsequent crops of grain and herbage. In feeding in this manner it is frequent to place in the field a little root with a cover containing a small quantity of hay which seems*

766

to be relished by the animals amid their mossier food.

<sup>5412.</sup> *In the feeding of oxen, the turnips may be laid down on a dry field, as in the case first mentioned but the proper and regular manner of feeding these animals is to supply them with the turnip in the house or open yard, littering them at the same time plentifully and regularly with straw and giving them what they choose to consume of it as provender, with their turnip-food. Cattle are fed either by being tied to upright posts in the house or they are suffered to go at large in the straw yard. This last is greatly the better mode of feeding the turnips being supplied from troughs or otherwise, and a shed for shelter being always at hand and open to the cattle to repose in. It is well, however, that too many animals, of different strength and size be not put together lest they disturb each other in feeding. Sometimes courts are made and divided into separate compartments, holding only two cattle in each, and this is found to be an exceedingly good practice. When cattle are of value, and put up for quick fattening, it is common to cut off the leaves and tails of the turnip, giving the leaves to the younger and less valuable stock, and the bulb only to that which is to be fed.*

<sup>5413.</sup> *Young cattle, not intended to be immediately fattened receive only a limited portion of turnips, their principal provender being straw. By receiving a portion of turnips with their drier provender these animals are kept in a much more healthy condition than if confined to the latter food and continue to grow throughout the whole season, instead of pining away at the time when green herbage can no longer be found for them. With the design too, of keeping them in a good condition turnips are supplied in a limited quantity to milch cows, and in particular at the time of calving. The turnip, however though it adds to the quantity of milk, gives it a strong and disagreeable flavour.*

<sup>5414.</sup> *When both sheep and cattle are fed upon a farm it is usual to pull up every alternate four or five rows of turnips for the cattle, leaving the remainder on the ground for the sheep, so that the land on which the turnips had grown may receive its proportion of the manure produced. (Quer Jour Ag vol. i. p. 296.)*

<sup>5415.</sup> *The advantages of sowing turnips on the place of their growth by sheep both in manuring and consolidating the ground are sufficiently well known to every farmer. One great defect of the inferior sort of turnip soil is the want of tenacity and it is found that valuable crops of wheat may be obtained upon very light porous soil as after turnips so consumed. It is not uncommon to let turnips at an agreed price, for each sheep or beast, weekly. This varies according to age and size and the state of the demand from four pence or less to sheep weekly, and from two shillings to five for each beast. An acre of good turnips say thirty tons with straw will sustain an ox or six sheep, or ten Leicester sheep. Supposing the turnips worth six guineas, this may bring the weekly keep of the ox to six shillings and three-pence halfpenny and of the sheep to about seven pence halfpenny a week. In this way of letting, however disputes may arise, as the taker may not be careful to have them eaten up clean. The person who lets the turnips has to maintain a herd for the taker, and when let for cattle, and consequently to be carried off the taker finds a man and horse, and the latter maintains both. The taker has to provide hurdles or nets for fencing the allotments to sheep, but the latter must fence his own holdings if necessary. The period at which the taker is to consume the whole is usually fixed in the agreement, that the seller may be enabled to plough and sow his land in proper season. (Suppl. to Encyc. Brit.) The rule for selling turnips in Norfolk is calculated from the fact, that one acre of good turnips is sufficient for 100 sheep for one week. Then, whether turnips be dear or cheap, the price per week may be easily found — at 3s per acre, 1s per week per head, and so of all other prices. This is under the supposition that the crop is to be eaten off on the ground.*

<sup>5416.</sup> *The Swedish and yellow turnips are eaten greedily by horses and afford a very nutritive and salutary food along with hay or straw for working stock. The best mode is to steam them after previously passing them through the slicing machine, as no root requires so much cooking as the Swedish turnip. Horses will also eat the white turnip, but not freely unless they have been early accustomed to them, as in some parts of Norfolk.*

<sup>5417.</sup> *Cattle fatten much faster with clean turnips than with such as are dirty, and therefore Wastell recommends that they should never be given without being previously washed. The earth upon unwashed turnips, he says, scours the cattle, and keeps their bodies too loose and open, their dung being thin and almost liquid, carries off with it a white mucous matter from the bowels, which is frequently seen among the dung the loss of which must necessarily retard the fattening of the cattle, but with washed turnips their dung is wax-like, and figured similarly to the dung of cattle fed on rich meadow hay. Cisterns are also found very useful in frosty weather, for when frozen turnips are thrown into spring water it speedily draws out of them all the icy particles, which when retained, must undoubtedly render them much less nourishing and improving to the cattle that eat them. (Wastell's Designs, &c. p. 40.)*

<sup>5418.</sup> *Near large towns the most profitable mode of disposing of turnips is to the cow-keepers and green-grocers.*

<sup>5419.</sup> *The application of turnips in domestic economy is well known. They may also be used in the distillery and a wine is said to be made from them by the London manufacturers of imitations of foreign wine.*

<sup>5420.</sup> *The storing of turnips is attended with too much labour and risk to be of much advantage in the greater part of the kingdom. Common turnips are never stored in any great quantity, though sometimes a portion is drawn and formed into heaps, like*

potato camps, and lightly covered with straw or preserved for some time under a shed. On these occasions, before storing up, the shaws or leaves and the tap-roots must be cut off and removed, to prevent heating and rotting. The heaps must not be covered with earth-like potatoes, for in this case their complete destruction is inevitable. This root contains too much water to be preserved for any length of time in a fresh and palatable state, after being removed from the ground and though the loss in seasons unusually severe, particularly in the *white globe* variety is commonly very great, it is probable that a regular system of storing the whole, or the greater part, of the crop every season would, upon an average of years, be attended with still greater loss besides the labour and expense, where turnips are cultivated extensively would be intolerable (*Supp. &c.*)

5421 *Taking up and replacing* is a mode by which turnips have been preserved by Rialtie of Holkham and some others. The mode is to cart the turnips from the field where they grow to a piece of ground near the farm-office, before the winter rains set in when the tap root being cut off, the plants are set on the surface of the ground in an upright position, so close to each other as they can stand where they keep much better than in a store during the whole season. The advantages of this is that they quite close to the horizontal in place of being their roots probably from a distant part of the turn in wet or stormy weather are so obvious as fully to justify a recommendation of the practice.

5422 *Replacing and earthing* have also been tried with success, especially with the Swedish turnip. Being pulled and freed from their roots and leaves, they are carted to a piece of well worked dry soil near the farmery and there deposited in rows so close as nearly to touch each other in the bottom of shallow furrows the plough covering one row as another furrow is opened. In this way many tons are quickly earthed in, and on a very small space, and they can be turned out when wanted with equal facility (*Farmer's Magazine* vol. xxii. p. 282).

5423 *The produce of turnips* cultivated in the broad-cast manner in England varies from five to fifteen tons per acre the latter is reckoned a very heavy crop. In Northumberland and Berwickshire, a good crop of white globe turnips drilled usually weighs from twenty-five to thirty tons per acre, the yellow and Swedish commonly a few tons less. Of late there have been instances of much heavier crops, and in Ayrshire it would appear that above sixty tons have been raised on an English acre, the leaves not included (*Farmer's Magazine*, vols. xv and xvi.) But such an extraordinary produce must have been obtained by the application of more manure than can be provided without injustice to other crops, from the home resources of a farm and where turnips form a regular crop in the rotation, no such produce is to be expected under any mode of culture.

5424 *The produce of the turnip in nutritive matter*, as proved by Sir H. Davy was forty-two parts in a thousand of which seven were mucilage, thirty four sugar and one gluten. Swedish turnips afforded sixty four parts in a thousand of nutritive matter of which nine were starch fifty-one sugar two gluten, and two extract. According to Von Theer, 100 lbs. of turnips are equal to twenty-two of hay and an ox to get fat on turnips ought to have one third of its weight daily.

5425 *To raise turnip seed*, the usual mode is to select the most approved specimens of the variety to be raised at the season when they are full grown and either to remove all others from the field and leave them to shoot into flower stems next year or to transplant them to a place by themselves, where they will be secure from the fumes of other plants of their genus. In either case they must be protected by earthing up from the winter's frost and rains, and in the ripening season from the birds.

5426 *The true sort of Swedish turnip* can very easily be kept by only attending to the plants when in flower. All the degenerated ones bear bright yellow flowers which should be pulled out before the seed ripens. The true sort have a brownish yellow flower. This saves the expense of transplanting if a corner or one ridge of a field can be found convenient for sowing.

5427 *The Norfolk seed growers* have a sort of theory on the subject of transplanting turnips for seed which it may be worth while to attend to. According to that theory where turnip seed is collected from such turnips as have been sown three or four years in succession the roots are liable to be numerous and long, and the necks or parts between the bulbs and leaves coarse and thick and when taken from such as have been transplanted every year these parts are liable to become too fine, and the tap-roots to be diminished in too great a proportion. Of course the most certain plan is to procure seed from turnips that are transplanted one year and sown the next or if they be transplanted once in three years. It is supposed that the stock may be preserved in a proper state of perfection. It is stated, that the method of performing this business in the best way is to select such turnips as are of the best kinds and of the most perfect forms from the field crops, and after cutting their tops off to transplant them about the month of November, or following month into a piece of ground that has been put into a brace of tillage by repeated ploughing or digging over and which should be situated as near the house as it can be in order that the birds may be better kept from it. The seed will mostly be ready for gathering in the end of July or in the following month.

5428 *Others cultivate* however advise that the seed collected from a few turnips thus transplanted should be preserved and sown in drills, in order to raise plants for seed for the general crop, drawing out all such as are weak and improper leaving only those that are strong and which take the lead and that when these have formed bulbs, such as do not appear good and perfect should be taken out as by this means turnip seed may be procured, not only of a more vigorous nature but capable of vegetating with less moisture, and of producing stronger and more hardy plants. The practice of transplanting the whole of the turnips for seed for the main crop, they contend, is not only highly expensive, but injurious by diminishing the strength of the plants from the destruction of their tap-roots. Very good seed may now ever be raised in either of the methods that have been here described.

5429 *The best Norfolk turnip seed growers* are of opinion that unless the seed be *always* saved from transplanted roots, the stock will infallibly degenerate in the manner here described. The statement it is transplanting once in three years is sufficient, was a more prevalent with some of the growers to enable them to save two thirds of the heavy expense which attends transplanting turnips, and to get the same price for their seed as if it had been properly saved. The only exception to this is in what the Norfolk farmers call the "padding" or "long peddling" turnip, which is too tender to bear the winter. For a stock a few sorts are taken up and protected from cold like mangelwurzel; and for a general crop the

seed is sown broadcast and not hoed, but suffered to grow like rape. So treated the plants form very small woody sorts, which are capable of enduring frosts (*J. L.*)

5430. *After the seed has become fully ripened*, it is mostly reaped by cutting off part of the stems, and afterwards tying them up into sheaves, which, when sufficiently dry are put into long stacks, and kept through the winter, in order to be threshed out about the time when it is wanted. But as in this way much seed is liable to be lost, by its readiness to escape from the pods in which it is contained, it is advised, as a much better practice, to have it immediately threshed out either upon a cloth in the field where it grew or in some other convenient place being then put into bags proper for the purpose and placed in a situation which is perfectly dry. From seed crops of this sort being subject to much injury and loss in different ways, the quantity of produce must be very different under different circumstances. But it may in general be stated at not less than from twenty to twenty-four bushels the acre. The price of turnip seed being seldom less than seven or eight shillings the bushel, on account of the great demand for it, it may at first appear to be a very advantageous sort of culture but from the exhausting nature of the crop, the loss sustained in grain, and the quantity of manure afterwards necessary it is probable that turnip seed can only be grown to advantage in particular circumstances of soil and situation. In most cases it is however well for the farmer to raise his own seed, as that of the shops is seldom to be fully depended upon.

5431. *The diseases and injuries to which turnips are liable* are various. At their first appearance their leaves are liable to the attacks of the fly (*Aphis* and *Haltica*), the caterpillar the slug, and the mildew. Their bulbs and roots are attacked by worms of different kinds by a singular tendency to monstrosity known provincially by the name of fingers and toes by the anbury by canker and by wasting or gangrene from water or frost. Of all or most of these injurious diseases it may be observed that they neither admit of prevention or cure by art. Under favourable circumstances of soil climate, culture, and weather they seldom occur therefore all that the cultivator can do is to prepare and manure his land properly, and in the sowing season supply water when the weather is deficient in showers or the soil in humidity.

5432. *The fly attacks the turnip when in the seed-leaf and either totally devours it, or partially eats the leaves and centre-bud, so as to impede the progress of the plants to the second or rough leaves. Whether the eggs of these flies are deposited on the plants or in the soil, does not appear to be ascertained in all probability they are attached to the former as in the gooseberry caterpillar and most cases of flies and insects which feed on plants. Preparations and mixtures of the seed, as already treated of are all that have yet been done in the way of preventive to this evil.*

5433. *The caterpillar makes its appearance after the plants have produced three or more rough leaves, as they eat through and either destroy or greatly impede the progress of the plants. There can be little doubt that the eggs of these caterpillars are deposited on the leaves of the plants by a species of moth as the caterpillar may be detected when not larger than diameter than a hair. As preventive to the moths from fixing on the turnips for a depository for their eggs, it has been proposed to place vessels with tar in different parts of the field the smell of which is known to be very offensive to moths and all insects or to excite a thick offensive smoke from straw or weeds to pass over the ground at the time when it is supposed the moths or parent flies were about to commence their operations. To destroy the caterpillar itself, watering with tobacco water lime water strong brine, and laying on ashes, barley straw &c. have been proposed.*

5434. *The slug and snail attack the plants both above and under ground, and eat both the leaves and roots. Boiling, salt, quicklime, &c. have been proposed to annoy them but the only effectual mode is, immediately after the turnips are sown to strew the ground with cabbage leaves, or leaves of any of the *Brassica* tribe. On these, especially if sweet from incipient decay the slugs will pasture, and may be gathered off by women or children every morning. If as many cabbage leaves, or handfuls of decayed pea haulm or any non-lar vegetable be procured, as will go over a ridge or two, say at the rate of a leaf to every square yard a whole field may soon be cleared by picking off the slugs and removing the leaves once in twenty-four hours. This mode we have found most effectual, and it is extensively practised by market and other gardeners. (*Key to Gard.* 2275.)*

5435. *The mildew and blight attack the turnip in different stages of its progress and always retard its growth. Its effects may be palliated by watering and strewing the leaves with sulphur but this will hardly be considered applicable to whole fields.*

5436. *The worms attack the roots and when they commence their ravages at an early period impede their growth and ruin or greatly injure the crop. They admit of no remedy or prevention.*

5437. *The forked excrescences known as fingers and toes in some places and as the anbury in others are considered an alarming disease and hitherto it can neither be guarded against nor cured. The following account of it is given by William Spence, president of the Holderness Agricultural Society in 1811.*

5438. *In some plants the bulb itself is split into several finger-like diverging lobes. More frequently the bulb is externally tolerably perfect, and the tap-root is the part principally diseased, being either wholly metamorphosed into a sort of misshapen secondary bulb, often larger than the real bulb, and closely attached to it or having excrescences of various shapes, frequently not unlike human toes (whence the name of the disease either springing immediately from its sides, or from the fibrous root that issues from it. In this last case each fibre often swells into several knobs, so as distantly to resemble the runners and accompanying tubers of a potato; and not seldom one turnip will exhibit a combination of all these different forms of the disease. These distortions manifest themselves at a very early stage of the turnip's growth and plants, scarcely in the rough leaf, will exhibit excrescences, which differ in nothing else than size from those of the full-grown root.*

5439. *The leaves discover no unusual appearance except that in hot weather they become flaccid and droop from which symptom the presence of the disease may be surmised without examining the roots. These continue to grow for some months but without attaining any considerable size the excrescences enlarging at the same time. If divided at this period with a knife both the bulb and the excrescences are found to be perfectly solid, and internally to differ little in appearance from a healthy root except that they are of a more mealy and less compact consistency and are interspersed with more numerous and larger sap-vessels. The taste, too, is more acid, and on this account, sheep neglect the diseased plants. Towards the approach of autumn the roots, in proportion as they are more or less diseased, become gangrenous and rot, and are either broken (as frequently happens) by high winds, or gradually dissolved by the rain. Some which have been partially diseased, survive the winter; but of the rest, at this period, no other vestige remains than the vacant patches which they occupied at their first appearance. There is no longer any doubt about the cause of this disease, it is the effect of the deposition of the eggs of a small fly (probably a *Scaphomyia*) into the pithy parts of the roots, and the albuminous parts of the bulb, which soon changing to a maggot, and ultimately to a perfect insect, eat their way out.*

5440. *For the prevention of this disease, marl has been recommended by Sir Joseph Banks and others and where marl cannot be procured, it has been thought that an addition of mould of any kind that has not borne turnips, will be advantageous, such as a dressing taken from banks, woodlands, ditches, &c. and mixed up with a good dose of lime. But lime alone has been tried in vain and no great dependence*

can be placed upon fresh mould, as this disease has been known to prevail upon lands that had scarcely sown before horse a crop of turnips (*Farmer's Magazine* vol. xxi.) The only effectual preventive would be to hinder the insect from laying its eggs.

5441. *The coney attacks the roots, and partly the bulbs, of turnips, and is known by the ulcerated appearance it produces. Some consider it owing to the presence of too much iron in the soil, and recommend liming as a preventive.*

5442. *Wasting and putrefaction, from excess of water or frost, are to be prevented by earthing up the bulbs, or taking up and storing.*

SECT. III. *The Carrot.* — *Daucus Carota* L. *Peridandria Dignia* L. and *Umbellifera* J. *Carotte*, Fr. *Gelbe Rube* Ger. *Carota* Ital. and *Chirivia*, Span.

5443. *The carrot is a biennial plant, a native of Britain but though long known as a garden plant, it is comparatively but of recent introduction in agriculture. It appears to have been cultivated from an early period in Germany and Flanders, and introduced from the latter country to Kent and Suffolk early in the 16th century. As the carrot requires a deep soil, inclining to sand, it can never enter so generally into cultivation as the potato or turnip but, as observed by a judicious writer it has been too much neglected on lands where it would have yielded a more valuable product, perhaps, than any bulbous or tap-rooted plant whatever. Several contradictory experiments in its culture have been detailed in a number of publications, from which the practical husbandman will be at a loss to draw any definite conclusion but, in a recent communication to the Board of Agriculture, from Robert Burrows, an intelligent Norfolk farmer who has cultivated carrots on a large scale, and with great success, for several years, so accurate an account is presented of the culture, application, and extraordinary value of this root, that carrots will probably soon enter more largely into the rotation of crops on suitable soils. (Supp. &c.) This person had more experience than any one but he, after a few years, discontinued to cultivate carrots so extensively as he did at the time the communication to the Board of Agriculture was made. The consumption of carrot seed in Norfolk had, in 1821 diminished from three or four tons a year to as many cwt.*

5444. *The varieties of carrot cultivated in gardens are numerous, and readily increased by the usual means but the only sort adapted for the field is the long red or field carrot. New seed is most essential, as it will not vegetate in the second year. Old seed or a mixture of old and new and also the mixture of the horn carrot, the seed of which is sent over in large quantities from Holland, ought to be carefully avoided.*

5445. *The best soil for the carrot is a deep rich sandy loam such a soil ought at least to be a foot deep, and all equally good from top to bottom. On any other the held culture of the carrot will not answer.*

5446. *In preparing the soil for the carrot it is essential to plough it before winter that it may be pulverised by frost and to work it well by the plough and cultivator in spring to at least the depth of a foot. This deep tillage may be perfectly accomplished either by means of the trench plough following the common one, or by the common one alone, with a good strength of team but the former method is to be preferred wherever the lands are inclined to be stiff or heavy. Three ploughs are mostly found sufficient, where the land has been previously in a state of tillage but more may in other cases be necessary. The first ploughing should be made to the depth of ten, twelve or fourteen inches, and be performed when the soil is tolerably dry about the beginning of October. It may remain in this condition till towards the middle of February when it should be turned over a second time, but in a cross direction to nearly the same depth. In March a third ploughing may be given in order to the putting in of the seed. This may be somewhat lighter than the preceding ones. As soon as the last ploughing has been given in March the land should be harrowed, and the surface made as fine as possible.*

5447. *In Suffolk the farmers sow carrots after turnips, barley and peas set upon a ryegrass ley the crops upon the first have generally been most productive next to that they prefer the latter. In the first place, they feed off the turnips by the beginning of February and then lay the land up in small balks or furrows, in which state it remains till the second week in March when it is harrowed down, double furrowed to the depth of about twelve inches, and the seed sown.*

5448. *The climate most suitable to the carrot is the same as for the turnip but, from the depth to which their roots penetrate, they will thrive better than the turnip in a dry and warm climate.*

5449. *Manure, according to some should not be given to carrots the year they are sown, as it is alleged that when the roots meet with it they become forked scabbed, and wormy. This, however, is chiefly applicable to cases in which recent unfermented manure has been given, or where other manure has not been properly broken in pieces and spread over the soil or in the drills. The Suffolk and Norfolk farmers, who are the best carrot-growers, always use dung, a suitable proportion of well rotted farmyard dung being constantly turned into the soil at the last ploughing in March for it has been fully shown, by various trials detailed in *The Annals of Agriculture* and other books on husbandry that though good crops of carrots may be occasionally grown without the use of manure, it is only by the liberal application of that substance that the greatest produce possible can be obtained as they are in general found to bear a relative proportion to the quantity that may have been employed.*

5450. *Burrows prepares the land with a good dressing of about sixteen cart-loads per acre of rotten farmyard manure or cottager's ashes the load is about as much as three able horses can draw, and, if bought, costs about four shillings and sixpence per load, besides the carting on the land. He usually sows*

wheat stubbles after clover ploughing the first time in autumn and once more in the early part of the month of February if the weather permits; setting on the manure at the time of sowing, which is about the last week in March or sometimes as late as the second week in April.

5451. In Suffolk, when carrots are intended to be sown after peas, they usually plough the stubble as soon as the harvest is over in order that the land may clear itself of weeds. In December it is laid up in small balks, to receive the benefit of the frosts, in February it is harrowed down, and manured at the rate of fifteen loads per acre the manure is ploughed in to the depth of about four inches and in the month of March the land is double furrowed and the seed sown. By pursuing this method they say the manure lies in the centre of the soil, and not only affords nourishment and support to the carrot in its perpendicular progress but renders it easy to be turned up by a single ploughing, and greatly promotes the growth of the succeeding crop of barley. In Norfolk it is the practice to sow carrots after a crop of turnips. The manure, after being put on the land in the beginning of March, is first ploughed in with a common plough and afterwards trench ploughed about fourteen or fifteen inches deep; it is then harrowed very fine and the seed sown about the middle of March.

5452. The season preferred by Burrows for sowing the carrot is the last week in March or first in April but he prefers the first period having generally found early-sown crops the most productive.

5453. The usual preparation of the seed for sowing is mixing it with earth or sand to cause it to separate more freely but Burrows adds water, turns over the mixture of seeds and moist earth several times, and thus brings it to the point of vegetating before he sows it. "Having weighed the quantity of seed to be sown, and collected sand or fine mould, in the proportion of about two bushels to an acre I mix the seed with the sand or mould, eight or ten pounds to every two bushels, and this is done about a fortnight or three weeks before the time I intend sowing taking care to have the heaps turned over every day, sprinkling the outside of them with water each time of turning over that every part of the sand heaps may be equally moist, and that vegetation may take place alike throughout. I have great advantage in preparing the seed so long beforehand it is by this means in a state of forward vegetation, therefore lies but a short time in the ground and, by quickly appearing above ground, is more able to contend with those numerous tribes of weeds in the soil whose seeds are of quicker vegetation." (Supp. &c.)

5454. Crude the French translator of Von Thier's work, describes in a note (tom. iv. 387) a practice nearly similar to that of Burrows. Crude uses sawe (sifted soil) instead of earth and waters with the drainings of dunghills. He keeps the mixture in a warm but shady situation for eight days by that time the seed is nearly ready to vegetate, and he sows it immediately.

5455. The quantity of seed when carrots are sown in rows is two pounds per acre, and for broad-cast sowing five pounds Burrows sows ten pounds per acre in the broad-cast manner.

5456. The usual mode of sowing the carrot is broad-cast but a much better mode in our opinion would be to sow them in rows at twelve or fourteen inches distance drawing the drills, and hoeing the intervals with any suitable drill and hoe.

5457. The most common practice when carrots are best cultivated is the hand or broad-cast method the seed being dispersed as evenly as possible over the land after the surface has been reduced to a very fine state of pulverisation by harrowing in order to provide a suitable bed for it to vegetate in; being then covered in by means of a light harrow. As the seed of the carrot is not of a nature to be deposited with much regularity by the drill and as the young plants can be easily set out to proper distances in the operation of hoeing this is probably the most appropriate method of putting such sort of seed to the ground; and an additional proof of it is indeed found in its being that which is almost universally adopted in those districts where carrot-husbandry is practised to the greatest extent. But with the view of having the after-culture of the crops more perfectly performed, and at the same time to save the great expense of hand labour in hoeing the crop the drill method has been attempted by some cultivators but we believe without complete success. The work is finished in equidistant rows at the distance of from two to fifteen or eighteen inches from each other according to the mode of hoeing that is practised. In this business some cultivators do not make use of drill-machines, but strike the land into small furrows by hoes or other implements contrived for the purpose, and then cast the seed over the ground by the hand, covering it in either by slight harrowing or hoing in the tops of the ridgelets. It is added, that "in this method where a drill-machine is used it has been advised by an intelligent cultivator to deposit the seed to the depth of one inch in the rows leaving the space of fourteen inches between them as intervals the seed in these cases being previously steeped in rain water for twenty four hours and left to sprout, after which it is mixed with saw dust and dry mould, in the proportion of one peck and a half of each to a pound of the seed. The land is afterwards lightly harrowed over once. Two pounds of seed in this mode are found, as it has been observed, sufficient for an acre of land."

5458. The after-culture given the carrot consists entirely of hoeing and weeding.

5459. In Suffolk they are hoed generally three times in the season. The first time, as soon as the plants can be distinguished from the weeds which surround them. The operation should be performed with three-inch hoes, having handles not above two feet in length and it requires great attention as it is extremely difficult to distinguish and separate the young carrots from the weeds. The second hoeing should be given in three or four weeks afterwards according to the forwardness of the crop it may be performed with common hoes care being taken to set out the plants at proper distances. From eight to fifteen or eighteen inches, each way are the common distances at which they are allowed to stand and it has been proved, from many years' experience in districts where they are most cultivated that carrots which grow at such distances always proves a more abundant crop than when the plants are allowed to stand closer together. The third hoeing is commonly given about the middle or end of June and in this, besides destroying the weeds another material circumstance to be attended to is, to set out the carrots at proper distances, and also, wherever any have been left double at the former hoeings to take the worse of the two plants away.

5460. Carrots sown according to the plan of Burrows are ready to hoe within about five or six weeks. He hoes three and sometimes four times or until the crop is perfectly clean. The first hoeing is with hoes four inches long and two and a quarter inches wide. The second hoeing invariably takes place as soon as the first is completed, and is performed with six-inch hoes, by two and a quarter inches wide. By this time the plants are set the first time of hoeing nothing was out but the weeds. He leaves the plants nine inches apart from each other sometimes they will be a foot, or even farther asunder.

5461 *Carrots are taken up generally in the last week of October* Burrows's practice is to let the work to a man who engages women and children to assist him. The work is performed with three-pronged forks, the children cut off the tops, laying them and the roots in separate heaps, ready for the teams to take away.

5462. "I take up in autumn a sufficient quantity to have a store to last me out any considerable frost or snow that may happen in the winter months the rest of the crop I leave in the ground preferring them fresh out of the earth for both horses and bullocks. The carrots kept bent in the ground nor can the severest frosts do them any material injury the first week in March it is necessary to have the remaining part of the crop taken up, and the land cleared for barley. The carrots can either be laid in a heap with a small quantity of straw over them or they may be laid into some empty outhouse or barn, in heaps of many hundred bushels provided they are put together dry. This latter circumstance it is indispensably necessary to attend to for if laid together in large heaps when wet, they will certainly sustain much injury. When selecting such as I want to keep for the use of my horses until the months of May and June I draw over the heaps (which should be done in the latter end of April, when the carrots begin to sprout at the crown very fast) I throw aside the healthy and most perfect roots, and have the crop as cut completely off and laid by themselves by this means, carrots may be kept the month of June out in a high state of perfection." (*Communications to the Board of Agriculture* vol vii p. 15.)

5463 *Storing a whole crop of carrots may be a desirable practice when winter wheat is to follow them, in which case the same mode may be adopted as for turnips or potatoes, but with fewer precautions against the frost, as the carrot, if perfectly dry is very little injured by that description of weather.*

5464. *The produce of an acre of carrots in Suffolk, according to Arthur Young is at an average 350 bushels but Burrows's crops averaged upwards of 800 bushels per acre, which considerably exceeds the largest crop of potatoes.*

5465. *The uses to which the carrot is applied in Suffolk are various. Large quantities are sent to the London markets, and also given as food to different kinds of live stock. Horses are remarkably fond of carrots and it is even said that when oats and carrots are given together the horses leave the oats and eat the carrots. The ordinary allowance is about forty or fifty pounds a day to each horse. Carrots when mixed with chaff, that is, cut straw and a little hay without corn, keep horses in excellent condition for performing all kinds of ordinary labour. The farmers begin to feed their horses with carrots in December and continue to give them chiefly that kind of provender till the beginning or middle of May to which period, with proper care, carrots may be preserved. As many of the farmers in that country are of opinion that carrots are not so good for horses in winter as in spring they give only half the above allowance of carrots at first, and add a little corn for a few weeks after they begin to use carrots.*

5466. *The application of the carrot to the feeding of working cattle and hogs is thus detailed by Burrows:—"I begin to take up the carrot crop in the last week of October as at that time I generally finish sowing my horses with lucern, and now solely depend upon my carrots, with a proper allowance of hay as winter food for my horses, until about the first week of June following when the lucern is again ready for sowing. By reducing this practice to a system, I have been enabled to feed ten cart horses throughout the winter months for these last six years, without giving them any corn whatever and have at the same time effected a considerable saving of hay from what I found necessary to give to the same number of horses, when, according to the usual custom of the country I fed my horses with corn and hay. I give them to my cart-horses in the proportion of seventy pounds weight of carrots a horse per day upon an average not allowing them quite so many in the very short days, and sometimes more than that quantity in the spring months, or to the amount of what I withheld in the short winter days. The men who tend the horses slice some of the carrots in the cut chaff or hay and barn-door refuse the rest of the carrots they give whole to the horses at night, with a small quantity of hay in their racks and with this food my horses generally enjoy uninterrupted health and I mention this, as I believe that some persons think that carrots only given as food to horses, are injurious to their constitutions but most of the prejudiced of mankind have no better foundation and are taken up at random, or inherited from their grandfathers. We successfully have I been with carrots, as a winter food for horses, that with the assistance of lucern fit sowing in summer I have been enabled to prove by experiments conducted under my own personal inspection that an able Norfolk team horse fully worked two journeys a day winter and summer may be kept the entire year round upon the produce of only one statute acre of land. I have likewise applied carrots with great profit to the feeding of hogs in winter, and by that means have made my straw into a most excellent manure, without the aid of neat cattle. The hogs so fed are sold on Norwich hill to the London dealers as porkers." The profit of carrots so applied he shows in a subsequent statement, together with an experiment of feeding four Galloway bullocks with carrots, against four others fed in the common way with turnips and hay. (*Communications* &c.)*

5467 *In comparing the carrot with the potato, an additional circumstance greatly in favour of the former is, that it does not require to be steamed or boiled, and it is not more difficult to wash than the potato. These and other circumstances considered, it appears to be the most valuable of all roots for working horses.*

5468. *The use of the carrot to domestic economy is well known. Their produce of nutritive matter as ascertained by Sir H. Davy amounts to ninety eight parts in one thousand, of which three are starch, and ninety-five sugar. They are used in the dairy in winter and spring to give colour and flavour to butter. In the distillery owing to the great proportion of sugar in their composition they yield more spirit than the potato the usual quantity is twelve gallons per ton. They are excellent in soups, stews, and hennets, and boiled whole with salt beef.*

5469. *To save carrot seed, select annually some of the most perfect and best-shaped roots in the taking-up season, and either preserve them in sand in a cellar till spring, or plant them immediately in an open airy part of the garden, protecting them with litter during severe frosts, or earthing them over and uncovering them in March following. The seed is in no danger of being contaminated by any other plant, as the wild carrot, even should it happen to grow in the neighbourhood, flowers later. In August it will be fit to gather, and is best preserved on the stalks till wanted. This is the most*

certain mode of procuring genuine and new seed, but still it will be found advisable to change it occasionally

5470 *The diseases of carrots* are only those which are common to most plants, such as mildew insects, &c. The mildew and worms at the root frequently injure crops, and are to be guarded against as far as practicable by a proper choice of soil, season of sowing, and after-culture

SECT IV *The Parsnep*. — *Pastinaca sativa* L. *Pentáandra Digyna* L. and *Umbellifera* J. Le Panou, Fr. *Pastinake*, Ger. *Pastinaca*, Ital. and *Zanahoria* Span.

5471 *The parsnep* is a biennial plant with a fusiform root like the carrot, and nearly equal in its products of nutritive and saccharine matter. It is a native of most parts of Europe and generally cultivated in gardens, but is only of late and very partial introduction as a field plant. Its culture has been chiefly confined to the Island of Jersey, where it attains a large size, and is much esteemed for fattening cattle and pigs. It is considered rather more hardy than the carrot, and its produce is said to be greater. It may be sown either in autumn or spring and its seed admits of drilling by machinery. The plants when they come up are more easily recognised than carrots, and consequently their culture is on the whole more simple, less dependent on manual labour and, therefore, more suited to farming. For the rest, their culture is the same as that of the carrot.

5472 *The variety best suited for the field* is the large Jersey the seed of which should be procured from the island as that of the garden parsnep sold by the seedsmen never attains the same size.

5473 *The soil, preparation, and manure* for this plant are the same as for the carrot.

5474 *The quantity of seed for sowing in drills* is from four to five pounds per acre, and for broad-cast six or eight pounds. It must always be new, as two years seed does not come up freely. It may or may not be prepared by steeping but it requires no earth or sand, or rubbing, like carrot seed, as it passes freely through the same drill that will sow tares or peas.

5475 *The time of sowing* is generally about the middle of February but some sow in September in which case the seed does not vegetate till early in spring. The latter method, however is obviously against the culture of the soil, which must thus remain a year in a consolidated state.

5476 *The manner of sowing* is generally in drills at fifteen or eighteen inches distance but some sow broad-cast, and harrow in the seed and in Jersey parsneps and beans are generally cultivated together. The beans are first dibbled in, and afterwards the parsnep seed scattered over the surface and harrowed. It is acknowledged that a good crop of both plants is never obtained, and therefore though this mode may be found to answer in the mild climate of Jersey, it is not to be imitated in other places. Drills and broad-cast without any intermixture of plants are the only advisable modes.

5477 *The after-culture and taking up* are the same as for the carrot, with this difference, that the parsnep when sown broad-cast is generally thinned out to twelve inches, at an average, plant from plant and, when in rows eighteen inches apart, to nine inches in the row.

5478 *The produce* is said to be greater than that of carrots and the economical application the same. In the fattening of cattle it is found equal if not superior performing the business with as much expedition and affording meat of exquisite flavour and a highly juicy quality. The animals eat it with much greediness. It is reckoned that thirty perches, where the crop is good will be sufficient to fatten a perfectly lean ox of three or four years old, in the course of three months. They are given in the proportion of about thirty pounds' weight morning noon, and night the large ones being split in three or four pieces, and a little hay supplied in the intervals of those periods. Indeed, the result of experiment has shown that not only neat cattle, but hogs and poultry, become fat much sooner and are more bulky than when fed with any other root or vegetable and that the meat is more sweet and delicate. The parsnep is excellent food for cows and, with hay during winter the cows of Jersey and Guernsey yield butter of a fine yellow hue, of a soft tinge as excellent as if they had been in the most luxuriant pasture. In these islands beans are cultivated along with parsneps, in double rows, twelve feet asunder, and the beans eighteen inches apart every way. The beans are planted first, and the ground afterwards harrowed, and the parsneps sown broad-cast. (*Com. to B. of Agr.* vol. 1 p. 215.)

5479 *Parsnep leaves*, being more bulky than those of carrots, may be mown off before taking up the roots, and given to cows, oxen, or horses, by which they will be greedily eaten.

5480 *The use of the parsnep in domestic economy* is nearly the same as that of the carrot. They are much esteemed to salt fish and are sometimes roasted for that purpose.

Their produce in nutritive matter is 99 parts in 1000, of which 9 are mucilage and 90 sugar. Gerarde says, that a very good bread was made from them in his time. They afford as much spirit as the carrot, and make an excellent wine.

5481 *To save parsnep seed*, proceed as with the carrot. The parsnep being more hardy and luxuriant than the carrot, is less liable to the mildew and worms, but equally so to become forked if the soil be not deep and well pulverised, and the manure minutely divided and equally distributed.

*Spec. V The Field Beet.* — *Bete L.*, *Pensée des Dégâts L.*, and *Chenopodium J. Beteraceae* Champêtre, Fr; *Mangold-wurzel*, Ger *Bettola*, Ital, and *Betarraja*, Span.

5482. *The field-beet*, commonly called the mangold-wurzel, and sometimes erroneously the root of scarcity (in German *mangel wurzel*), is supposed by Professor Thier to be a mongrel between the red and white beet. It has a much larger bulb than either and that bulb, in some varieties, grows in great part above ground. It has been a good deal cultivated in Germany and Switzerland, both for its leaves and roots: the leaves are either used as spinach or given to cattle and the roots are either given to cattle, used in distillation, or in the manufacture of sugar. The culture of the field-beet in Britain is very recent, and it may be questioned whether it has any advantages over the turnip for general agricultural purposes. It admits, however, of being cultivated on ridgelines and with as little manual labour as the turnip, while it will prosper on a stronger soil and near large towns it is not liable to the depredations usually committed on turnips or carrots, as the root is unpalatable either raw or boiled.

5483. *The variety preferred* in Germany is one slightly tinged with red for cattle, and the pale yellow variety for the distillery and sugar manufacture. The seed must not exceed a year old, and great care should be taken that the seed of the common red and white beet are not mixed with it. The seed of every variety of beet is very apt to degenerate.

5484. *Any soil* will suit this plant provided it is rich: immense crops have been raised on strong clays but such soils are not easily prepared for this sort of crop, and are also ill adapted for after-culture.

5485. *The preparation* should be exactly the same as for turnips; and the seed should be sown on the ridgelines in the same manner. Some, however, double in the seed in order to save the expense of thinning. The season of sowing is the same as for the parsnep, and should not be deferred later than the middle of April. The after culture consists in hoeing, hand-hoeing, and weeding, as in the culture of the turnip, and the plants are thinned out to about the same distance in the rows. Plants may be filled up by transplanting, or as in the case of the Swedish turnip, whole crops may be reared in this way but the produce is never so large. As the transplanting, however, takes place in May more time is afforded, and drier weather obtained for cleaning the soil. The plants are set by the dibbler along the centre of the ridgelines, which are previously consolidated by rolling.

5486. *The produce is, ceteris paribus*, about the same as that of the Swedish turnip but the nutritive matter afforded by the beet is 136 parts in 1000, of which 13 are mucilage, 119 sugar, and 4 gluten. According to Von Thier they afford ten per cent. of nutritive matter, and are in that respect to hay as 10 to 46 and to potatoes as 50 to 46. An acre would thus appear to afford more nourishment than turnips, carrots, or parsneps.

5487. *Fractional sown* are not agreed as to the value of this root, compared with the Swedish turnip, but the majority seem to think, that as a food for milk cows, the mangold is to be preferred, more especially as it gives no unpleasant taste to the milk and butter. It has this advantage over turnips, that it thrives better than they do in a dry warm season, being a plant that naturally requires more light and heat than the turnip.

5488. *The application of the field-beet* is almost confined to the fattening of stock, and feeding of milk cows. Near London they are in repute for the latter purpose and, according to Von Thier they cause a great increase of milk as well as improve its flavour. The tops are first taken off, and given by themselves and then the roots are taken up, washed, and given raw. The roots are much more easily injured by frost than the turnip, carrot, or parsnep, and are stored with difficulty. The leaves make a very good spinach, but the roots cannot be used in cooking like those of the red beet. In the distillery it is nearly half as productive as the potato but, according to Von Thier, it is not likely to yield much profit in the manufacture of sugar.

5489. *The manufacture of sugar from mangold wurzel* is still, however, carried on in France, and although we think it can never ultimately compete with that from the cane, it seems of late years to be on the increase. We shall therefore give a short account of the process, presuming that the greatest quantity of sugar is not obtained from the greatest bulk of root, but rather from small roots produced from dry calcareous soils, at the rate of from fifteen to twenty five tons an acre. One cwt. of sugar is the general produce obtained by the most perfect apparatus from one ton of root. As soon as the leaves begin to turn yellow the root may be said to have arrived at maturity and it is time to take up the crop, and to begin the process of sugar-making, an operation which continues from October to February in the larger manufactories. Take the roots up dry and keep them so; the smaller the heap the better because the least fermentation will effectually prevent the formation of sugar. The difference in amount and quality of sugar is always in favour of that made at the beginning of the season. The root, in keeping, undergoes a chemical change, often amounting to a total loss of its saccharine matter; although its outward appearance indicates no such change.

5490. *Process of sugar-making.* The roots should first be washed, and then rasped to reduce them to a state of pulp. Of course in large manufactories, they are provided with rasping machines and it is

somewhat difficult to find a substitute on a small scale. I should imagine, though, that a stout iron plate, punched with triangular holes, the rough edges of which are left standing, somewhat after the manner of a nutmeg-grater might answer the purpose, only that I would have it somewhat concave instead of convex. Upon the rough side of this plate I would rub the roots by hand. If there should be a cider-mill and press within a reasonable distance, it might answer to take the roots thither, slice them and pass them through the mill. When by these or any other means they are reduced to pulp the juice should be pressed from the pulp which is thus done — It is put into canvas bags not too fine so as to impede the running of the juice, nor yet so coarse as to let the pulp through the meshes. The bags should be so fitted as, when pressed, to occupy about an inch in depth. Most manufactory use about twenty-five of these bags at one pressing, but this depends on the power of the press. Between every bag of pulp is laid a sort of oiled hurdle to allow the juice to percolate freely from the press into the juve cistern below. The operation of pressing should immediately follow that of ransping. This point should be particularly attended to.

5491. *Defecation.* The juice being expressed from the pulp, the next process is the defecation of the juice, and here too, no time should be lost. This is effected by boiling, a copper boiler should be used. Get up the fire till the thermometer indicates 170° or 175°. Then add sifted lime (quick) previously mixed with water at the rate of five or six pounds for every 100 gallons of juice. Stir it well up, and when the liquor heat it till the thermometer reaches 240°. Add sulphuric acid in small portions, diluted with six times its bulk of water to neutralise the effect of the lime, stirring it briskly each time. The proper quantity is ascertained by carefully examining the juice every time the acid is added with a drop of syrup of violets in a spoon, which ought to turn of a green colour. About thirty ounces of the acid to every 100 gallons of juice will be necessary. This done, the fire is quenched, and the boiler left to settle for half an hour at the end of which time, the liquor is drawn off by some, bullock's blood is added when the temperature of the juice reaches 190° in the proportion of two pints and a half to every twenty gallons of juice. Some, too, apply the sulphuric acid to the juice when cold, instead of hot, viz. before the boiler fire is lighted; and one recommends its being applied to the pulp before it goes into the boiler but all this practice will decide.

5492. *Concentration.* The next process is concentration of the juice, which means nothing more than evaporating from it the water therein contained. This is effected by flat pans, over a brisk fire but not so as to burn the syrup, which is the great danger in this operation. When reduced in pan 1 from 4 to 2 inches or so in depth, it is put into a smaller pan (2) and reduced to the same depth, and after wards into a third pan. These three removals are the work of an hour and a half. If the syrup rises, and threatens to overflow the pan, put in a small lump of butter which will make it subside.

5493. *Clarification.* This the next operation and may be carried on in one of the pans used for concentration. Animal charcoal (some have even used wood charcoal) is now applied, at the rate of half a pound for every gallon of syrup, which renders it perfectly black and muddy. In this state, add blood mixed with water (sifted up well with the syrup) in the proportion of about a pint and a half of blood to every twenty gallons of syrup.

5494. *Boil it a short time,* after which it is filtered, and then boiled again, care being taken not to burn the pan. Great care is necessary in examining the state of the syrup from time to time. The thermometer ought to stand as high as 234° on attaining which, the pan should be emptied eighteen gallons of syrup will be reduced, by boiling, to eleven gallons. The syrup is next cooled to a suitable vessel to 180° or 190° and then run into moulds but the cooling is very gradual. The pan is so eroded, and the heat kept in by closing the edges with damp. The syrup is then poured into large earthen moulds cone-shaped, and with a hole at bottom through which the molasses drains. This hole is temporarily stopped till the mould is full. A mould contains ten or twelve gallons and requires a month to purge itself. As it cools it crystallises. The syrup, whilst filling is at 67° to 77° but in the course of purging it is raised to 190° and even 140° which expedites the flow of the molasses. Our next process is *turning the moulds* i. e. setting the corners out their bases, and taking them out of the moulds. (The point of the cone; moist and syrupy this is cut off and boiled over again with the molasses. Thus far the process of making brown sugar refining is a different business, and one which there is no occasion to particularise here. It is to be observed, that copper utensils are preferred to those of iron the latter having a chemical effect on the sugar. (*Gard. Mag.* vol. vi. pp. 150 151.)

5495. *To save seed* select the finest specimens, preserve them in sand during winter and plant them in an airy part of the garden in March. The rest is easy

5496. *To diseases* no plant is less liable than the best.

SECT VI. *The Cabbage Tribe* — *Brassica* L. *Tetradymia* Sibthorp L., and *Cruifera* J. Chou, Fr *Kohl*, Ger ; *Cavolo* Ital ; and *Col*, Span

5497. *The cabbage tribe* is of the greatest antiquity in gardens, and most of the species may be cultivated in the fields with success. For the common purposes of farming, however, there can be little doubt that they will afford less profit than any of the plants hitherto treated of in this chapter but near large towns or sea-ports they may answer the purpose of the farm-gardener. Cabbage culture, Brown observes, is much more hazardous, far less profitable, and attended with infinitely more trouble, than that of turnips while the advantages to be derived are not, in our opinion, of a description to compensate the extra hazard and trouble thereby incurred.

5498. *The culture of cabbage* has been strongly recommended by several speculative agriculturists and examples adduced of extraordinary produce and profits but any plant treated in an extraordinary manner will give extraordinary results, and thus an inferior production may be made to appear more valuable than it really is. One reason why so much has been said in their favour by Arthur Young and other southern farmers, is, that they compare them with the produce of turnips which, in the south of England, is averaged at only fifteen tons per acre

5499. *The variety of cabbage*, cultivated in the fields for cattle, is almost exclusively the large field cabbage, called also the Scotch, Strasburg drumhead, &c For the purposes of domestic economy other varieties of early and late cabbage, as the York, Rattier, sugar-loaf imperial, &c are grown and also German greens, Savoy cabbage, and even Brussels sprouts and broccoli

5500. *The cow cabbage*, *Cassarea cole*, or *tree cabbage* (*Brassica cheirazon* L. var. *arborescens* Des.; *Chou arboresc* Chou à cochon, Chou branche, Chou en arbre Chou mille tiges, Fr ; *Camel* Flaxa.), is much cul-

stained for milk cows in French Flanders, the Netherlands, and in Jersey and Guernsey and it has been introduced, at different periods, into this country without having ever come into general cultivation. The *Chou comble de Flandre* differs from the French variety in having red leaves, and the *Chou over-branche*, the *Chou mille tête de Fontenay*, differs from the first in not growing quite so high, and in forming a somewhat tufted head. No variety among these, and the many that might be named appear so suitable for field culture in the climate of Britain as the Scotch or drumhead cabbage.

5501. In Jersey the *one* cabbage is sown from about the fifth of August to the 1st of September in a good soil, and planted out from November to January in succession, at from twenty to thirty inches distance, in a good, substantial, well manured soil as no plant is more exhausting, or requires a better soil, but perhaps no one plant produces so large a quantity of nutriment during its period of vegetation. About the month of April they begin (from the first crop) to strip the under leaves; cut them in small pieces mix them with sour milk and bran or other farinaceous substances and give them as food to ducks, geese, hogs, &c. During the whole summer they continue stripping the plant as above stated, until it attains the height of from six to twelve feet; and if a scarcity of forage prevails, the green leaves form excellent food for cows and oxen, with alternate feeds of hay and straw. The tops and side shoots are excellent at table during winter and spring. The longest of the stalks are frequently used to support scarlet runners and other French beans, and as cross rafters for farm buildings, under thatch and have been known to last more than half a century when kept dry for the latter purpose. (*Gard. Mag.* vol. v.)

5502. Any soil that is rich will suit the cabbage, but a strong loam is preferred. The best mode of preparation for field cabbage is that for potatoes or turnips, the plants being dibbled along the centre of each ridgelet. For early cabbage no ridgelets are required, as the plants are inserted in rows, by a line, at much narrower distances.

5503. The season for planting, for a full crop of field cabbages, is usually March but cabbages may be planted as late as June, and produce a tolerable crop by November, and in this way they may sometimes be made to succeed an unsuccessful sowing of turnips. The plants used in March should be the produce of seed sown, in an open loamy part of the garden, in the preceding August but those planted in May or June may be the produce of seed sown in the February or March of the same year.

5504. The preparation given to the plants consists in pinching off the extremity of their tap-root, and any tubercles which appear on the root or stem, and in immersing the root and stem in a puddle, or mixture of earth and water to protect the fibres and pores of the root and stem from the drought. The plants may then be inserted by the dibber taking care not to plant them too deep, and to press the earth firmly to the lower extremity of the root. If this last point is not attended to in planting by the dibber the plants will either die, or if kept alive by the moisture of the soil or rain their progress will be very slow. When the distance between the ridgelets is twenty-seven inches, the plants are set about two feet asunder in the rows; and the quantity required for an acre is about 6000 plants. Some recommend sowing as for turnips but, by this mode one of the advantages of a green crop is infringed on, viz. the time given to clean the land. Where cabbages are sown that operation must be performed at least a month sooner than if they were planted consequently the best month of the cleaning season is lost. To plant or sow a green crop on land in good heart, that does not require cleaning, will seldom be found good husbandry. It may succeed near large towns, where roots and other green produce sell high, but it can never enter into any general system of farming.

5505. The after-culture consists in hoeing and hand-hoeing and weeding and the crop is taken by chopping off the heads with a spade, leaving an inch or two of stalk to each. They may be preserved by housing, but only for a short time. The produce is said to be from thirty-five to forty tons per acre. Sir H. Davy found that 1000 parts of cabbage gave seventy-three of nutritive matter, of which forty-one are mucilage, twenty four saccharine matter and eight gluten.

5506. The application of the field cabbage is generally to the feeding of milk cows, and sometimes to the fattening of oxen and sheep. For the former purpose, great care must be taken to remove the outside decaying leaves otherwise they are apt to give an unpleasant flavour to the milk and butter. Cabbages are also eaten by swine and horses, and are reckoned excellent food for sheep that have newly dropped their lambs, and for calves. A cow will eat from 100 to 150lbs of cabbage per day, and a sheep ten or twelve pounds, besides a moderate allowance of hay. Some farmers consider that ewes fatten faster on cabbages than on turnips, and that ewes having lambs are much more prolific in milk when so fed. (*Country Times*, Feb. 8 p. 17.) Early or garden cabbages are sold to green-grocers, or to the consumers, or to shops victuallers for the purpose of being pickled or made into sour crout.

5507. *Salted cabbage, or sauerkraut*, is thus prepared in Germany:—Any sort of cabbage or hail or even turnips and kidney-beans, may be prepared in this way; but white compact-headed, large cabbages are preferred, and next compact-headed red cabbages. The first process of preparing them is to scoop out the interior part of the stalk with an iron instrument or scoop; they are then cut into small shreds by a wooden machine, composed of a flat board or tray which has a ledge on two sides, to steady a box or frame into which the cabbages are put. In the middle of the board are four flat pieces of steel, similar to the steel part of a spokeshave, placed in an oblique direction; and the near side of each being a little raised up, with small spaces between each, to let the shreds fall down into a tub placed underneath to receive them. The cabbages are then put into the box before described, which is pushed backwards and forwards, when the cabbages, being cut by the steel, fall in small shreds into a tub placed below. A barrel stands by ready to receive them when cut, the sides of which are first washed with vinegar. A man stands on a stile by the barrel, with clean wooden shoes on, whose business it is to salt and prepare them, which is done in the following manner: the man first takes as much of the cut cabbage as covers about four inches above the bottom; he next strews upon it two handfuls of salt, one handful of unground pepper, and a small quantity of dried oil; he then gets into the barrel, and treads it down with his wooden shoes till it is well mixed and compact. He next takes another layer of cabbage, and puts salt and pepper on it as before, and treads it again, and so goes on till the barrel is filled. A board is then placed on it, and upon the board some very heavy weights are put; and it remains so ten or fifteen days, when it partially decays, and a great deal of water swims on the surface: it is then put into the cask for use. The men

who prepare wurmkraut are Tyrolese, and carry their machines (fig. 767) which has not been invented more than ten or twelve years, on their backs from house to house. This machine contains a cutting tray (a) box into which the cabbages are placed (b) scoop (c) and tub into which the shreds fall (d). (*Gent Mag.* vol. lii. p. 345.)

5508. *Newton's machine for chopping cabbage or other vegetables, roots or meat* (fig. 768) consists of five knives let into an iron plate, and the latter is screwed to the working bar. The knives are fastened, by bolts passing through them, close under and above the iron plate. The sliding plate is for the purpose of preventing the meat from being scattered, and to this plate are added scrapers which are screwed underneath for the purpose of cleaning the knives at every stroke. A spring raises the knives and enables any person to chop at least twenty times as much meat in the same time, as can be done by the common mode. The length of the knives being equal to the breadth of the trough, no meat can possibly escape the knives, nor will the meat require so much turning as is usually wanted. When it does require turning, it is easily done by alternately pressing the knives at either end of the trough, sliding them towards the middle. The machine is also applicable for cutting fat, suet, &c. previously to rendering them into tallow; likewise to chopping madder and other roots for calico printers, or as used in their recent state for dyes; and for dividing potatoes, carrots, and other esculent roots, cabbage for sauer kraut and roots used in feeding cattle. (*Smith's Mechanics*, vol. ii. p. 560.)

5509. To save cabbage seed, select a few fine specimens, and plant them by themselves where they will be in no danger of being contaminated by others of the *Brassica* tribe when in flower. The seed will keep many years.

5510. The diseases of cabbages are the same as those of the turnip, with the exception of the forked excrescence. On the roots of the plants are frequently found knobs which in the preparation for transplanting, should, as we have already observed, be carefully removed.

#### SECT. VII. Other Plants which might be cultivated in the Fields for their Roots or Leaves, as Food for Man or Cattle, in a recent State.

5511. Every hardy garden plant may be cultivated in the fields, and with very little manual labour. Accordingly we find onions, spinach, cress, radishes, and even cucumbers, grown by farmers, or farm gardeners in the neighbourhood of the metropolis, and also in other places. None of these plants however can be considered as belonging to agriculture, nor should we notice those which follow but because they have been tried and recommended by zealous cultivators, and are treated of in some works on farming. No plant can be considered as belonging to agriculture that is not in sufficient demand, or of sufficient general use in feeding stock, as to admit of its frequent occurrence in rotations and such certainly cannot be said to be the case with the Jerusalem artichoke and lettuce, now about to be noticed.

5512. The *Jerusalem artichoke* (*Helianthus tuberosus* L., *Topinambour* Fr.) is a tuberous-rooted plant, with leafy stems from four to six feet high. It thrives well on soft moist soils, and even it is said, on moist peat soils and it is alleged that its tops will afford as much fodder per acre as a crop of oats, or more, and its roots half as many tubers as an ordinary crop of potatoes. (*Agricultural Magazine* 1807, p. 3.) The soil may be cultivated in all respects like the potato. The tubers, being abundant in the market gardens, are to be had at little more than the price of potatoes. The fibres of the stems may be separated by maceration and manufactured into cordage or cloth and this is said to be done in some parts of the north and west of France as about Haguenau, where this plant, on the poor sandy soils, is an object of field culture.

5513. The common *Chicory* (*Lactuca sativa* L.) has been grown for feeding pigs, and other purposes. Arthur Young informs us, in his *Calendar of Husbandry* that he first observed the sowing of lettuce for pigs mentioned, on a pretty regular system, on the farms of a very intelligent cultivator (not at all a whimsical man) in Essex. He had every year six or ten, which afforded a great quantity of very valuable food for his sows and pigs. He adds, that it yields milk amply and all sorts of swine are very fond of it and he thinks that the economical farmer who keeps many hogs should take care to have a succession of crops for these animals, that his carts may not be for ever on the road for purchased grain, or his granary opened for corn when more than is necessary. To raise this sort of crop, the land should have been ploughed before the winter frosts, turning in by that earth twenty loads of rich dung per acre, and making the ridges of the right breadth to suit the drill machine and horse-hoe, so that in the month of March nothing more may be necessary than to scarify the land and to drill the seed at one foot equidistant, at the rate of four pounds of seed per acre. Where the stock of swine is large, it is proper to drill half an acre or an acre of lettuce in April, the land having been well manured and ploughed as directed above, being also sowed in February and March, and well harrowed and repeated before drilling, and at this period, the crop which was drilled in March (a succession being essentially necessary) should be turned in the rows by hand, to about nine or ten inches asper. If this necessary attention be neglected the plants, he says, draw themselves up weak and poor, and will not recover it. Women do this business as well as men. When about six inches high they should be horse-hoed with a scarifier or scuffle having the hoe about four inches, or at most five inches in width. With this sort of green food, some kind of meal or other dry meat should be combined, so without it it is apt to prove very laxative. This success cultivator is not likely to be followed by any rent-paying farmer who can grow any of the clovers, turnips, or potatoes. The quotation affords a good specimen of Arthur Young's mode of writing on agricultural subjects.

5514. The chicory will endure or succory (*Cichorium Intybus* L. *Cichorée sauvage*, Fr. fig. 769) has long thick, perpendicular roots, a tuft of endive or lettuce-looking leaves, and when it shoots into flower its stems rise from one to three feet high, rigid, rough, branched, and clothed with leaves and blue flowers. It is found wild in dry calcareous soils in England, and in most parts of Europe of similar or greater temperature. It is cultivated in France as an herbage and pasture plant, and in Germany and Flanders for its roots from which a substitute for coffee is prepared. It was first cultivated in this country about 1780 by Arthur Young, who holds it in very high estimation. It is of such consequence, he says, for different purposes of the farm, that on various sorts of soil the farmer cannot, without its use, make the greatest possible profit. Where it is intended to lay a field to grass for three, four or six years, in order to rest the land, or to increase the quantity of sheep food, the farmer cannot, he thinks, be any hesitating in using it. There is no plant to rival it. Lucern he says demands a rich soil, and will always be kept as long as it is productive, but upon inferior land it is not an equal object. Upon blowing sands or upon any soil that is weak and poor and wants rest, there is no plant, he supposes, that equals this. On such sort of blowing poor sandy lands as many districts abound with, especially in Norfolk and Suffolk, it will yield a greater quantity of sheep food than any other plant at present in cultivation. On fen and bog lands, and peat soils it also thrives to much profit. On all land where clover has long been too often repeated is apt to fail chicory may be substituted to great advantage. It does very well for soiling cattle, both lean and fatening. It is of excellent use for those who keep a large stock of swine, and it does exceedingly well in an alternate system of grass and fallow, as it will last four, five, six, and even more years, but it should

not be sown with any view of making hay in this climate, though it forms a considerable proportion of many of the best meadows in the south of France, and in Lombardy. It has, however, he adds, been objected to, on the ground of its rising and becoming a vivacious weed in succeeding crops, and if this circumstance be not guarded against, it will he says, happen. But more than with lucern or so much. But who, he asks, ventures to forbid chicory culture on account of this quality which is really founded on its merit? When the land is ploughed twice he, only use a broad sharp share, and burrow in tares for feeding or soiling, or break it up for run in, and there is an end of the objection.

5515. The culture of chicory is the same as of clover. As the plant is grown in gardens for culinary purposes, the seed may be procured in the seed shops, gathered in many places from wild plants, or saved by the grower. It is small, flat, black, and resembling that of lettuce. It should be procured fresh, and from eight to twelve pounds an acre are usually sown. The culture of this plant for its roots has been noticed in giving the outline of the agriculture of Flanders and will be adverted to in a succeeding Chapter.

5516. The rough comfrey (*Symphytum aspernum* L. fig. 770) a perennial from Siberia has been brought into notice by D. Grant, a nurseryman at Lewisham, and tried by a number of cultivators. Cattle of every kind are said to be fond of this plant and so great is its produce on good soil, that Mr Grant thinks an acre might be made to produce thirty tons of green fodder in one year. He has grown it to the height of seven feet as thick as it could stand on the ground. The plant is of easy propagation by seed or division of the roots, the better way would probably be to sow in a garden, and transplant when the plants were a year old. All the symphytums are plants of great durability so that this species, if once established, would probably continue to produce crops for many years, and in that point of view it would seem to be a valuable plant for the cottager who keeps a cow (*Gard. Mag.* vol. v. and *Country Times*, May 10th 1830.)

5517. The day lily (*Homocallis fulva* L., fig. 771) was brought into notice by Mr Eden, late of Longford. In the year 1806, he observed, accidentally how extremely fond cattle were of this plant, even eating it down to the roots when an opportunity occurred, and as he knew, from long experience, that it would, even in dry ground, produce herbage in the muck and litter and of

769

770

April, equal in quantity to any water meadow the extreme facility with which it may be propagated and grown in almost any soil and situation and also its apparently nutritious nature, he was induced to give it a trial in a plot of ground of about twenty rods, attached to the cottage in which he lived. He did so, and after two years' trial found the day lily produce a supply of green food in April and towards the middle of May, when there is little or no pasture grass, and he was could detect any unpleasant flavour in the milk or butter though given in considerable quantities. The day lily, of which there are two species differing very little in appearance, *H. alba* and *fovea*, is a perennial of great duration rapid increase and of easy propagation by division. It certainly well deserves trial as a permanent herbage plant, especially for the cottager and small farmer (*Gard. Mag.* vol. v. p. 441)

## CHAP. V

### Culture of Herbage Plants.

5518. *The cultivation of clovers and other herbage plants*, used exclusively as food for live stock, is comparatively a modern improvement. They were known, as we have seen to the Greeks and Romans, and cultivated from a very early period in the low countries but do not appear to have attracted much notice in Britain till the sixteenth century when our frequent intercourse with Holland led to the introduction of some of our best field plants and agricultural practices. At present clovers enter largely into the succession of crops, on all soils, and in every productive course of management. Before they were introduced into cultivation, it was necessary, when land was exhausted by grain crops, to leave it in a state of comparative sterility for several years, before it became either valuable as pasture or again fit for carrying corn but at present clovers are not only indispensable in the cultivation of white and green crops alternately, upon very rich soils, but are the foundation of convertible husbandry on land that is not so rich as to permit of a constant aration, and which therefore requires two or more years' pasturage at certain intervals. Lucern and sainfoin, though of much less value as general crops, are valuable plants in particular situations more especially the latter which will produce good crops on dry chalky and limestone soils where most other agricultural plants, and even grasses, would barely maintain their existence.

5519. *The characteristic points of culture* of this class of plants are broad-cast sowing, mowing, sodding and hay making and that when cut for the two last purposes, two or more crops may be had in a season from the same roots.

5520. *The nutritive products* of the principal herbage plants are thus given by Sir H. Davy —

Systematic Name.	English Name.	In 1000 Parts.				
		Whole quantity of soluble or nutritive matter	Moisture, or starch.	Sancharine matter or sugar	Gluten, or albumen.	Extract, or matter rendered insoluble during evaporation.
<i>Trifolium pratense</i>	Red clover	39	31	3	2	3
<i>medium</i>	Cow clover	39	30	4	3	2
<i>repens</i>	White clover	32	29	1	3	5
<i>Medicago Onobrychis</i>	Sainfoin	39	28	2	3	6
<i>Medicago sativa</i>	Lucern	23	18	1	—	6

5521. *The Clover Family* — *Trifolium* L. *Diadelpsis Decandria* L., and *Leguminosæ* J. *Trèfle*, Fr; *Klee*, Ger; *Trifoglio*, Ital., and *Trebol*, Span.

5521. *The clovers* (fig. 772.) are a numerous family, chiefly natives of Europe those selected by the agriculturist are natives of Britain and one species, the white or creeping clover is often found in great luxuriance in native pastures. As rye-grass is very generally sown with clovers, it will be necessary to treat of its culture in connection with these plants, reserving, however the more particular consideration of rye-grass till we treat of the hay grasses. (Chap. VI.) Many intelligent cultivators consider rye-grass as a very severe crop for the soil and it is alleged that wheat does not succeed well after the herbage with which rye-grass is intermixed in any considerable quantity. Other plants have accordingly been recommended as a substitute for rye-grass, and cock o-foot (*Dactylis glomerata*) has been tried, apparently with great success, by Coke of Holkham in Norfolk, and others but this is a very coarse grass when allowed to run to any height, and the use of it for hay has not yet been ascertained. Donaldson considers the general introduction of clovers, and the cultivated grasses, as one of the greatest improvements in modern husbandry. The commencement of improvements in the different species of live-stock, in the modes of cultivation, and in the superior quality, as well as quantity, of the crops of grain may all, he thinks, be dated from the period when the sowing of clovers and grass-seeds was first introduced into the different districts of the kingdom.

\*5522. The species of clover in cultivation are —

5523. The red clover (*Trifolium pratense*, fig. 772. a) a biennial, and sometimes, especially on chalky soils, a triennial plant, known from the other species by its broad leaves, luxuriant growth and reddish purple flowers. In its wild state a perennial.

772. The white, or creeping or Dutch clover (*T. repens*, b) a perennial plant, known by its creeping stems and white flowers.

5525. The yellow clover hop-trefoil or shamrock clover, the black unsuck of the Norfolk farmers (*T. pratense* c) an annual, known by its procumbent shoots and yellow flowers. This species is seldom cultivated: the yellow clover of the seed shops being the *Medicago lupulina*, the lupuline or unette clover of the French (fig. 773.)

773

5526. The meadow clover cow-clover cow-grass or marsh grass, the first the best name (*T. medium*, d) a perennial resembling the red clover but of a paler hue dwarfier habit with pale red or whitish flowers, and long roots very sweet to the taste. This species is but partially cultivated and it is extremely difficult to procure the seeds genuine. It comes into flower from twelve to fifteen days later than the common red clover has a solid stalk, a narrower leaf, and both leaves and flowers have a paler hue. A poor sandy soil it is said will produce a good crop of cow clover that would not produce half a crop of the common red clover. It is also a good second year as the first. Some farmers sow it because the crop comes in between the first and second cutting of the red clover as green food.

\*5527. The flesh-coloured clover (*Trifolium incarnatum* Lin. *Torouche* or *Trefle de Roussillon*, Fr. fig. 774) has long been cultivated in some of the southern departments of France and, though an annual is found very advantageous on dry sandy soils. The Agricultural Society of Nancy have lately recommended it for culture in the province of Lorraine and a writer in the *Journal des Lays Bas*, as suitable to many parts of the Netherlands. M. de Dumbaulc, a theoretical and practical agriculturist in great estimation, sows it, after harvest, in the stubbles, with no other culture than harrowing in. It grows all the winter and early in spring affords abundant food for sheep or if left till May it presents a heavy crop for the scythe, and may be used for soaking, or making into hay (*Gard Mag* vol. iv p. 392 and vol. v p. 734.) It was introduced into England about the year 1824, by Mr John Ellman, jun. of Southover near Lewis, who gives directions for sowing it in March without a corn crop, and states that it will be in full bloom and fit to cut by June. He says it is very productive, but should not be sown with corn like other clovers, because it grows so fast as to choke them. (*Farm Jour.* March 17 1828.)

774

5528. *Trifolium Molinieri* (with yellow flowers) *compensate* also with yellow flowers, and *fragiferum*, are cultivated in France but we believe chiefly in the poorest soils. Seeds of them and of all the other species may be correctly obtained from Vilmorin, Andreux and Co. seed merchants in Paris.

\*5529. In the choice of seeds the red or broad clover is the kind most generally cultivated on land that carries corn and herbage crops alternately as it yields the largest produce for one crop of all the sorts. White and yellow clover are seldom sown with it, unless when several years' pasturage is intended.

5530. The soil best adapted for clover is a deep sandy loam, which is favourable to its long tap-roots but it will grow in any soil, provided it be dry. So congenial is calcareous matters to clovers, that the mere strewing of lime on some soils will call into action clover-seeds, which it would appear have lain dormant for ages. At least this appears the most obvious way of accounting for the well known appearance of white clover in such cases.

5531. The climate most suitable for the clovers is one neither very hot nor very dry and cold. Most leguminous plants delight both in a dry soil and climate, and warm

temperature, and the clover will be found to produce most seed under such circumstances but as the production of seed is only in some situations an object of the farmer's attention, a season rather moist, provided it be warm, is always attended by the most bulky crops of clover herbage.

5532 *The preparation of the soil and the manures*, which clover receives in ordinary farm culture, are those destined also for another crop clover mixed with a certain proportion of rye-grass being generally sown along with or among corn crops, and especially with spring sown wheat, barley, and the early varieties of oats. Unless, however, the soils on which these crops are sown are well pulverised, and have been some years under tillage, clovers will not succeed in them, it being ascertained that newly broken-up leys or pasture grounds cannot be sown down or restored to clover and grasses till the soil is thoroughly comminuted, and the roots of the former grasses and herbage plants completely destroyed.

5533 *The time of sowing clover-seeds* is generally the spring, during the corn seed time, or from February to May but they may also be sown from August to October and when they are sown by themselves, that is, unaccompanied by any corn crop, thus will be found the best season as the young plants are less liable to be dried up and impeded in their progress by the sun than when sown alone in spring and remaining tender and unshaded during the hot and dry weather of July

5534 *Some prepare the seed for sowing* by steeping in water or in oil as in Switzerland, and then mixing it with powdered gypsum, as a preventive from the attacks of insects.

5535 *The manner of sowing* is almost always broad-cast. When sown with spring corn, clover and grass-seeds are usually put in immediately after the land has been pulverised by harrowing in the corn-seed, and are themselves covered by one course more of the harrows or if the corn is drilled, the small seeds are sown immediately before or after hand-hoeing and the land is then finished by a course of the harrows. Clover is generally sown by hand, though of late years the broad-cast drill (p. 782) has been used, both in the case of the clovers and the grasses. A lighter harrow is generally employed in covering such seeds than that used for corn. When the land is under an autumn sown crop of wheat or other grain, though the clovers and rye-grass are still sown in spring, the proper period must depend both upon the state of the land and the progress of the crops, and it may be often advisable to break the crust formed on the surface of tenacious soils, by using the harrow before the clovers are sown as well as afterwards to cover them. Sometimes the roller only is employed at this time, and there are instances of clover and rye grass succeeding when sown without either harrowing or rolling. But it is commonly of advantage to the wheat crop itself to use the harrow in spring and the roller alone cannot be depended on unless the season be very favourable. In some cases grass-seeds are sown by themselves, either in autumn or spring but rarely on tillage land. Nature has not determined any precise depth for the seed of red clover more than other seed. It will grow vigorously from two inches deep, and it will grow when barely covered. Half an inch may be reckoned the most advantageous position in clay soil a whole inch in what is light or loose. It is a vulgar error that small seed ought to be sparingly covered. Misled by that error farmers commonly cover their clover seed with a bushy branch of thorn which not only covers it unequally but leaves part on the surface to wither in the air.

5536 *In the operation of sowing* some consider it best to sow the clover and rye-grass separately alleging that the weight of the one seed, and lightness of the other are unfavourable to an equal distribution of both.

5537 *The quantity of seed sown on an acre* is exceedingly various not only when more or less white or yellow clover is sown along with grass-seeds and red clover or when pasturage is intended but, even when they are the only kinds sown the quantity is varied by the quality of the soil, and the different purposes of hay, sowing, or one year's pasture, to which the crop is to be applied. When pasture is the object, more seed ought to be allowed than is necessary when the crop is to be cut green for scilling and for hay less may suffice than for either of the former. Finely pulverised soils do not require so much seed as clays, on which clover and rye-grass are very frequently sown among autumn or winter-sown wheat, when there is more danger of a part of it perishing from being imperfectly covered. In general eight or ten pounds may be taken as the minimum quantity though there have been instances of good crops from less and from that to fourteen pounds or more per English statute acre. Rye-grass, commonly at the rate of a bushel per acre but in many cases only half or two thirds of a bushel, is mixed with this weight of clover and both are sown at the same time. The rye-grass may be either of the perennial or annual variety as it is understood that the herbage is to be continued for only one year and the annual is sometimes sown in preference as producing a bulkier crop than the perennial.

5538 *When it is intended to retain the land in pasture for several years* the quantity of red clover is diminished, and several kinds of more permanent herbage are added, the most common of which are white and yellow clover and rillwort. No general rule can be laid down as to the proper quantity of each of these kinds in some cases red and white clover are sown in equal proportions and in others the latter is made greatly to predominate. The yellow clover and rillwort are not often sown at the rate of more than two or three pounds per acre. It is scarcely necessary to add that, in this case the rye-grass should always be of the perennial sort.

5539 *In the selection of clover and rye-grass seeds* particular attention should be paid to their quality and cleanness the purple colour of the clover seed denotes that it has been ripe and well as seed and the seeds of weeds may be detected in it by narrow inspection if there are any but various noxious weeds are frequently mixed up with the seeds of the rye-grass, which it is difficult either to discover or to separate from them. Between the seeds of the annual and perennial rye grass the difference is hardly discernible and therefore, unless it is of his own growth, the cultivator must depend in a great measure on the character of the person from whom he purchases it. Red clover from Holland or France has been found to die out in the season immediately after it has been cut or pastured while the English seed produces plants which stand over the second, many of them the third, year (*General Report of Scotland* vol. i. p. 537) thus remaining in the latter case four summers in the ground from the time of sowing.

5540 *The after-culture of clover and rye-grass* consists chiefly of picking off any stones or other hard bodies which may appear on the surface in the spring succeeding that in which it was sown and cutting off by the roots any thistles, docks, or other large grown weeds. After this the surface should be rolled once to smooth it for the scythe. This operation is best performed in the first dry weather of March. Some give a top-dressing of soot, gypsum common lime peat, or wood-ashes, at this time or earlier

gypsum has been particularly recommended as a top-dressing for clovers, and the other herbage legumes; because as their ashes afford that substance in considerable quantities, it appears to be a necessary ingredient of their food. Dutch ashes (427) have been strongly recommended as a top-dressing for red clover and they also contain gypsum; but where the soil is in good heart, and contains calcareous matter, any description of top-dressing, though it may be of advantage when it does not interfere with the general economy of the farm, cannot be considered necessary (*Supp. E. Div. art. Agr.*)

5541 The taking of the clover, or clover and rye-grass crop, is either by cutting green for soiling, by making into hay, or by pasturing. It is observed in *The Code of Agriculture*, that it is a most important point to ascertain in what cases cutting or feeding, is more beneficial. If fed, the land has the advantage of the dung and urine of the pasturing stock, but the dung being dropped in irregular quantities, and in the heat of summer when it is devoured by insects, loses much of its utility. If the dung arising from the herbage, whether consumed in soiling, or as hay, were applied to the land, in one body, and at the proper season, the operation would be more effectual. The smother of a thick crop, continued for any time upon the ground, greatly tends to promote its fertility, and it has been pretty uniformly found, after repeated trials, upon soils of almost every description, that oats or any other crop taken after clover that has been cut, either for soiling or hay, is superior to the crop taken after clover pastured by sheep.

5542 *Soiling* is a term applied to the practice of cutting herbage crops green for feeding or fattening live stock. On all correct management, the clover is cut green, for the wintering of horses, often for milch cows, and, in some instances, both for growing and fattening cattle. There can be no doubt of the advantages of this practice, in regard to horses and cows but for young and for fattening beasts, a sufficient number of experiments are not known to have been yet made with any great degree of accuracy. Young animals require exercise in the open air and probably will not be found to thrive so well in houses or stalls, during summer as on pastures, and though in every case there is a great saving of food, the loss, woolly and comparatively small stock of the plant, with leaves always more or less withered, are perhaps not so valuable in the production of beef on fattening stock as a much smaller weight of herbage taken in by pasturing. Milch cows, however are so impatient of heat and insects, that this way of feeding them, at least for a part of the day in warm weather, ought to be more generally adopted; and the convenience of having working horses always at hand, besides that they fill their stomachs speedily, is of not less importance than economy. (See *Comments on the Board of Agriculture*, vol. vi. *Brown's Treatise on Rural Affairs* vol. ii. *General Reports of Scotland*, vol. ii. and iii.)

5543 In feeding cattle with green clover attention must be paid to prevent swelling, or bloat, which is very apt to take place when they are first put on this food, especially if it is wet with rain or dew and cattle are exposed to this danger, whether they are sent to depasture the clover or have it cut and brought home to them. Though, if the plants are somewhat luxuriant, the danger is greater in the former case. After being accustomed to the rich food for a few days, during which it should be given rather sparingly, the danger is much diminished, but it is never safe to allow much cows, in particular to eat large quantities of wet clover.

5544 The making herbage plants into hay is a process somewhat different from that of making hay from mowed grasses. All the herbage tribe ought to be mown before the seed is formed, and indeed before the plants have fully blossomed, that the full juice and nourishment of the herb may be retained in the hay. By the adoption of this system, the hay is cut in a better season, it can be more easily secured, and is much more valuable. Nor is the strength of the plant lodged in the seed, which is often lost. The great advantage of converting under ripe herbage and grass into hay is now beginning to be known. I have seen much more nutritious matter in it, and it is consequently greatly more nutritious. A crop of clover or subclover, when cut in the early part of the season may be ten per cent. lighter than when it is fully ripe but the loss is amply counterbalanced, by obtaining an earlier, a more valuable, and more nutritious article while the next crop will be proportionably more heavy. The hay made from old herbage which has ripened its seed will carry on stock, but it is only hay from herbage cut when young and soon after it has come into flower that will fatten them. When the stems of clover become hard and woody by being allowed to bring these seeds towards maturity they are of little more value as provender than an equal quantity of the finer sort of straw of corn.

5545 The mode of making clover-hay and that of all herbage plants, as practised by the best farmers, is as follows.—The herbage is cut as close to the ground and in as uniform and perfect a manner as possible with a sharp scythe. The surface having been in the preceding spring freed from stones and well rolled, the stubble after the mower ought to be as short and smooth as a well shaven grass-lawn. The part of the stems left by the scythe is not only lost, but the after-growth is neither so vigorous nor so weighty as when the first cutting is taken as low as possible.

5546 As soon as the result of row of cut herbage is thoroughly dry above, it is gently turned over (not scudded or scattered) without breaking it. Sometimes this is done with the hand, or with a small fork and some farmers are so anxious to prevent the swath from being broken, that they only permit the use of the rake shaft. The grass, when turned over in the morning of a dry day is put into cocks in the afternoon. The mode of performing this is very simple and expeditious, and none but women, boys, and girls, under the eye of a confidential servant, are usually employed. If the crop is heavy a row of cocks is placed in the middle ridge of three, and if light of five ridges. A distinct company of carriers and rakers is allotted to every such number of ridges, and the separate companies proceed each on its own ground, and in the same manner as in reaping grain, which occasions a degree of competition among them for despatch, clean raking, and neat well-built cocks. The carriers gather the hay and carry it to the ridge where the cock is to be built by one of the most experienced hands. A raker follows the carrier taking up and bringing to the cocks the remains of the swath. There may be, in general, about five people employed about such row of cocks—a carrier and raker on each side of the ridge on which the cocks are placed, and a person on the ridge, who builds them. But when the crop is not weighty more rakers are required, as a greater space must be gone over.

5547 As the cocks are thus placed in a line it is easy to put two or more into one afterwards and the larger cocks may be speedily drawn together to be put into tramp-ricks, by means of ropes thrown round their bottoms, and dragged along by a horse. It is impossible to lay down any rules for the management of hay after it is put into cocks; one thing is, however, always attended to, not to shake out, scatter, or expose the hay often than is necessary for its preservation. Sometimes the cocks have been put up so large that they never require to go to a tramp-rick, but are carted to the stack-yard without ever being broken, and put up in alternate layers with old hay. But where this is attempted, there must not be much clover. The practice of mixing the new with the old hay is, however, a good one, and saves a great deal of time and labour at the same time that the old hay is much improved by the mixture.

3518. The first managers disapprove of spreading out the swath of clover and ryegrass, though this is after necessary with natural grasses, which are cut and harvested later in the season. The more the swath is kept unbroken, the hay is greener and the more flagrant.

3519. Another mode of hay making, said to have been originally practised in Lancashire, has been found to answer well in the moist atmosphere of the west of Scotland. This is called tipping or ripling; and if the grass is dry the operation begins as soon as it is mown. In making a tipple, a person with his right hand rakes the swath towards, until he has a little bundle; then the same is done by the left, until both meet and form eight or ten pounds or nearly so. This bundle is then set up against the legs, or between the feet, a rope is twisted of the grass, while the bundle is supported in this manner and tied round it near its top, and from the top are drawn up a few straggling stems, which are twisted to make the tipple taper to a point, and give it as much a conical shape as possible. If the crop is strong, there is a row of tipples placed on each swath; if light, two of these are put into one row. After standing a few hours, they become so smooth on the outside, that the heaviest rains seldom wet them through; and when wet, they are soon dried again in good weather. As soon as ready they are put into the summer-stack, or if very dry, even into the winter stack, but are never opened out or tedded, to make them dry they never require it. By this method not a blade is lost, and the hay is nearly as green as a leaf dried in a book. In a moderate crop, one woman will tipple to one mower and a woman will rake to two tipplers or two swathers. But where the crop is strong it may require three women to keep pace with two mowers. After the hay is put up in this manner the crop may be considered secure, though it may continue wet weather for a considerable length of time. (*General Report of Scotland*, vol. ii. p. 11.)

3520. The making of clover hay as practised in Courland, and adopted from that country to Silesia, is said to save not only a number of hands, but the hay is better and more nourishing. The hay is prepared by self-fermentation whereby it retains its nutritious juices, and only loses its watery particles. It is dried more expeditiously by dissipation of its humidity and contraction of the sap-vessels, and thus its nutritious juices are concentrated. The process is conducted on the following principle, viz. the sap-vessels are expanded by the circulation of the liquid juices by heat, and the superfluous humidity is exhaled on cooling, the sap-vessels contract, and thus future intensive fermentation is prevented, and the nutritious quality is preserved.

3521. The clover intended for hay after having been mowed remains till four o'clock in the afternoon of the following day in swath to dry, it must then be raked together into small coils, and afterwards made into large cocks in the form of a sugar loaf and such as it would require six or seven horses to remove. To prevent the air from penetrating these cocks, and to produce a quicker fermentation they must, whilst forming be trodden down by one or two men. If it be a still, close warm night, the fermentation will commence in four hours, and manifest itself by a strong honey like smell when proper fermentation is begun, the cocks will, on being opened smoke, appear brownish and may then be spread abroad. If in the morning the sun is warm, and a little wind arises the clover hay will quickly dry, it may then towards noon be turned with the rake or pitch-fork, and about four in the afternoon will be sufficiently dried, so that it may be immediately carted into the barn without any danger of a second fermentation. By this method of management, the clover will require only three days, from the time of mowing to its being housed, and very little work, whilst, in the common way, even in good weather it requires six or eight days. In the old method it frequently becomes of a black colour, but in the new method it is only brown, has an agreeable smell, and remains good and unchangeable in the barn. The farmer has also another advantage, that if he has not carts enough to carry it into the barn, he need only at sun-setting, heap it again to large well trodden cocks, and that he then with straw in which state they will remain the whole summer without damage or loss. This clover-hay is not only greedily eaten by sheep and lambs, but also by horses, calves, and cows.

3522. The same mode of making hay depends principally upon two circumstances. First, that the mown clover when brought together into large heaps, may ferment equally and expeditiously; secondly that the day succeeding the fermentation be dry sunny and windy on this account it may be proper to point out what should be done when circumstances are unfavourable. Let us suppose therefore, that the night after the clover grass has been placed in the great cocks is cold, damp, or rainy the fermentation will yet take place, although it may require a term of twelve, sixteen or twenty-four hours to effect it. If it be a second or a third crop, at which season the nights are colder it may even require from thirty to forty eight hours before the fermentation commences, it will, however, commence, and may be ascertained from this circumstance that you can scarcely bear your hand in the interior of the cock. Even if the night be dry yet if a strong cold wind blows, the cock may not ferment equally, but only in the middle, and on the side opposite to the wind; the other parts may still remain green. In such a case the following rules must be attended to.

3523. *Rule first.* If the cock has only fermented in the middle, and on that side where the cold wind did not act upon it, the whole heap must nevertheless be opened on the following morning. That which has already fermented must be separate and spread to dry it must be turned towards noon, and may be carted into the barn in the evening but that part of the cock which has not fermented must be again put together into large cocks, and fermented in the same manner as the preceding part, after which it may be spread to dry and brought into the barn.

3524. *Rule second.* In such cases where a small portion of the cock has fermented thoroughly but not the greater part, the heap must be spread abroad in the morning, but must be again made into a close cock in the evening, in such a manner that the part which has fermented be placed at the top or outside of the cock, and that which has not fermented be inclosed within it then on the ensuing morning or if the weather be cold and rainy on the morning afterwards the clover-heap may be again spread abroad and the clover trodden as in the case first mentioned.

3525. *Rule third.* If in spreading the heap abroad, it be found that nearly the whole of the clover has fermented, it will not be necessary to delay the housing of the whole on account of some small portion but the clover may be dried and carted into the barn. The small portion which remained unfermented will not occasion any disaster to the other which has fermented; for there is a material difference betwixt hay thus managed, and the meadow-grass which is brought whilst damp, or wet with rain into the barn, which will grow musty and putrid.

3526. *Rule fourth.* In such instances, where some of the cocks of clover have thoroughly fermented, and it rains on the morning, they ought to be spread abroad for the clover must be opened and spread, even if it rains violently, since if it were suffered to remain longer in the heap, it would take fire, or its juices would be injured by too much fermentation, the leaves and stalks would become black, and the clover must far from being better. The clover which has been spread must be turned from time to time, but not carted into the barn till dry. This drying takes place, if the rain discontinues for a few hours, much more expeditiously with the clover which has fermented than with that made in the common way. Besides which it must be remarked, that the fermented clover remains good, even if it continues some weeks exposed to the rain provided it is at last suffered to dry before it is put into the barn; otherwise the wet from the rain will render it rank and bad. The clover which has been so long a time exposed to the rain will not, however, be so nutritious as that which has been well fermented and sooner dried; but it will be far superior to the clover which has been exposed to the rain, and got up in the common method. (*Klopman in Thier's Annalen*, &c.)

3527. Hay is stacked in circular or oblong stacks, the latter form being most generally approved of, and carefully thatched, as has been already observed in regard to corn. It is never advisable to allow this kind of hay to become heated in any considerable degree, in the stack, though a slight oxidation, with a

very gentle warmth, is usually perceptible both in the field-ricks and in the stacks, for a few days after they are built. But this is a quite different thing from that intentional heating, carried so far in many instances, as to terminate in conflagration.

5559. The after-growth or second crop of clover is vigorous or weak, according to the proportion of clover sown to rye-grass, to the time when the first crop was cut, and to the moisture and warmth of the season. When the first cutting has been made early for eating, there will sometimes be three cuttings in one season. The first of these after-cuttings may be made into hay, and sometimes the second, but in general both are consumed by selling or pasturing, unless in some dry warm districts, as Norfolk, and parts of Bedford, Kent, &c., where the second growth is left to ripen its seed. In the northern counties the second crop is seldom made into hay owing to the difficulty of getting it thoroughly dried at a late period of summer when other more urgent operations usually employ all the labourers of a farm. If it is cut for this purpose, the best method of drying it is to mix it up with straw which will absorb a part of its juices. It is often cut green, as a part of the silage system; or where a sheep stock is kept, pastured by the old ewes, or other sorts, that are to be fattened the ensuing winter on turnips.

5560. In consuming clover and other herbage plants by pasturing or eating down on the spot, three methods have been adopted—tethering, hurdling, and free pasturage.

5561. Tethering may be considered a rude practice, and is chiefly confined to the north of Scotland and Ireland. In *The Agricultural Report of Aberdeenshire* it is stated that there are some cases where the plan of tethering can be practised with more profit than even selling. In the neighbourhood of Peterhead, for instance, they tether milch cows on their grass fields, in a regular and systematic method moving each tether forward in a straight line, not above one foot at a time, so as to prevent the cows from trampling on the grass that is to be eaten, care being always taken to move the tether forward like a person cutting clover with a scythe, from one end of the field to the other. In that way a greater number of cows can be kept, on the same quantity of grass, than by any other plan except where it grows high enough to be cut and given them green in houses. In one instance, the system was carried to great perfection, by a gentleman who kept a few sheep upon longer tethers, following the cows. Sometimes, also, he tethered ewes afterwards upon the same field, which prevented any possible waste for the tufts of grass produced by the dung of one species of animal will be eaten by those of another kind without reluctance. This system was peculiarly calculated for the cow-feeders in Peterhead, as, from the smallness of their holdings, they could not afford to keep servants to cut, or horses to carry home, the grass to their houses, to be consumed in a green state. (Code)

5562. In hurdling of clovers or herbage crops a portion of the field is enclosed by hurdles, in which sheep are confined; and as the crop is consumed, the pen is changed to a fresh place, until the whole is fed off. This practice is very extensively adopted at Fifehead, and is peculiarly calculated for light and dry soils. Its advantages are, that the grass is more economically consumed, that the stock thrive better, having daily a fresh bite; and that the dung falls, being more concentrated, is more likely to be of use.

5563. In the common pasturing of clover, the stock are introduced into the field earlier than in tethering or hurdling, in order to avoid the loss that would be sustained by cattle or sheep treading *ad libitum* on tall herbage. Indeed, the principal advantage of pasturing clovers is, that sheep and lambs may be turned on them more early than on common grass-lands. Sometimes this advantage is taken for a month or six weeks, in the beginning of summer and the field afterwards shut up for a crop of hay, but more frequently the red clovers are only mown. When white and yellow clovers are sown, the herbage is sometimes not mown at all, but pastured for three years or more, and sometimes a little red clover being sown along with these, a crop of hay is taken the first year.

5564. The produce of clover-hay, without any mixture of rye-grass, on the best soils as from two to three tons per acre, and in this state in the London market it generally sells 90 per cent. higher than meadow-hay, or clover and rye-grass mixed. The weight of hay from clover and rye-grass varies, according to the soil and the season from one ton to three tons per English acre, as it is taken from the tramp-ricks, but after being stacked, and kept till spring, the weight is found to be diminished twenty-five or thirty per cent.

5565. The value of clover and rye-grass hay in comparison with the straw of beans or peas, may be in the proportion of three to two, and with the finest straw of corn crops, in the proportion of two to one. One acre of red or broad clover will go as far in feeding horses or black cattle as three of ordinary pasture, and when it is cut occasionally and given to them fresh, it will, probably go still much farther, as no part of it is lost by being trodden down. With the exception of lucern, and the herbage of rich marshes, there is no crop by which so much stock can be supported as by clover. It may be profitably employed in fattening sheep in spring and with this food they will soon be ready for the butcher. Afterwards, a crop of hay may be got, and two or three weeks after the hay has been taken off sheep intended to be fattened on turnips may be turned in, and kept there, until the turnips are ready for them.

5566. The nutritive products of clovers will be found in the table. (5590.)

5567. The sowing of clover seed is attended with considerable labour and difficulty. Clover will not perfect its seeds, if saved for that purpose early in the year, therefore it is necessary to take off the first growth either by feeding or with the scythes, and to depend for the seed on those heads that are produced in the autumn. Seed clover turns out to good account in those years when the crops are not injured by the blight, which is often fatal to them, or by the rains in the autumn, which sometimes prove their destruction for the time of harvesting this seed falling out late when rainy weather may be expected, renders it, on that account, very tedious.

5568. When the first crop is fed off it is eaten till about the end of May, frequently by ewes and lambs; and this is understood to be an advantageous practice, because the land is less exhausted, and the green food is of great value for stock in the spring months. It is not uncommon however to cut the first growth for a hay crop, and this should be done earlier than usual. The growth thus reserved for seed must be suffered to remain till the hanks become perfectly brown, when it is cut and harvested in the usual manner, leaving it on the field till it is very dry and crisp, that the seeds may become more fully hardened. It may then be laid up dry to be thrashed out at the farmer's convenience. Much labour and expense are necessary in separating the seed from the capsule or seed-coat, especially when it is affected by thrashing, which seldom costs less than five to six or seven shillings per bushel. By the use of mills the work may be done much cheaper.

5568. *The management of a crop of clover with a view to saving seed* is thus given by a cultivator in Buckinghamshire. A moderate bulk of haulm is generally found most productive of seed, and a moderately rich sharp, dry soil is the best for having moderate haulm. The field may be pastured till the middle of May and then shut up till the ripening is completed. August is generally the ripening month, and the maturity of the seed may be known by the leaves becoming brown and dropping off. Deserve the seed from time to time, and when it has changed from a bright yellow to a deep purple, it is then ready for the scythe. After the crop is cut down, disturb it as little as possible by fork or rake. Turn it into small cocks not larger than musk hoppers. Should favourable weather ensue nothing more is necessary than to turn these cocks once over shortly before carting home. And should the weather prove chilly, these small heaps of withered straw are very soon dried, perhaps in one good day by turning up the bottom after the top has become a little dried. After remaining some time in the field the cocks subside considerably and become caked, by which the flowers adhere together and repel the rain. Of course no loss of top can be sustained by gently turning them to dry. It thus appears, that clover for seed is not so liable to be injured as clover for hay. In general six or ten days of favourable weather render it fit to carry to the rick-yard and stack. It may either be threshed by a light fall, or by threshing machines, having a particular additional cover introduced below the drum or beater for that purpose.

5569. *In threshing* whether by the fall or machine, the first operation is to separate the heads or spikes of seeds from the haulm. This operation separates some of the seed which remains firm in the withered florets and requires to be separated by a course of light thrashing, similar to that used for hummelling barley. When on examination it is found that the seed is all separated, the operations of sifting and winnowing ought to be carried on in the usual manner with appropriate sieves. The clover sieve being well known to the sieve-maker. The average produce per acre is three hundred weight.

5570. *Seed may be saved from a second crop*; that is, after the first crop has been mown for hay, but the sample is seldom so strong or plump as that from a first crop.

5571. *White clover* and also yellow clover, lucern, and saintfoin when intended for seed, are treated much in the same manner as red clover (*Form. Mag.* vol. xix. p. 276.)

5572. *The produce in seed* may generally be from three to four or five bushels per acre, when perfectly clean weighing from two to three hundred weight. But there is great uncertainty in the produce of clover seed, from the lateness of the season at which it becomes ripe and the fertility of the soil is considerably impaired by such a crop. Yet the high value of the seed is a great inducement to the saving of it, in favourable situations. (*Dickson's Practical Agriculture*, vol. ii p. 863.)

5573. *The diseases of clover* are the blight or mildew and suffocation or consumption, from insects, slugs, and worms. It often happens that clover after being repeated at short intervals on the same soil, either fails or does no good whether that is owing to a disease, or to a defect of some peculiar substance which enters into the food of the plant, does not appear to be clearly ascertained. A top-dressing with ashes or lime is said to be unfavourable to the slug but where vermin of this sort are very numerous, the most certain remedy is a naked fallow well worked in the hottest months.

SECT II *Lucern*. — *Medicago sativa* L. *Diadelphea Decandrina* L. and *Leguminosae* J. *La Lucerne* Fr., *Futterklee* Ger., *Medica*, Ital., and *Mielga* Span. (fig 775.)

5574. *Lucerne* is a deep-rooting perennial plant, sending up numerous small and tall clover like shoots, with blue or violet spikes of flowers. It is a native of the south of Europe, and appears to be acclimated in the warmer parts of England. Lucerne or medic is highly extolled by the Roman writers, and also the cyprus, the latter a low evergreen shrub. Lucerne is much grown in Persia and Lama, and mown in both countries all the year round. It is also of unknown antiquity in old Spain, Italy and the south of France. It was introduced to England from the latter country according to Miller in 1657. It is mentioned by Harthib Blythe, and other early writers, and was tried by Lisle, but it excited little attention till after the publication of Harts's *Essays*, in 1757. It is now only cultivated in a few places, and chiefly in Kent. Columella estimated lucerne as the choicest of all fodder, because it lasted many years, and bore being cut down four, five or six times a year. It enriches, he says, the land on which it grows, fattens the cattle fed with it, and is often

a remedy for sick cattle. About three quarters of an acre of it, he thinks, abundantly sufficient to feed three horses during the whole year.

5575. *Clover has found no great reception in this country* though it was so much esteemed by the ancients, and has been long cultivated to advantage in France and Switzerland. If any good reason can be given for this, it is, that lucerne is a less hardy plant than red clover requires three or four years before it comes to its full growth, and is for these and other reasons ill adapted to enter into general rotations. Where the climate and soil suit, perhaps a field of it may be advantageously sown, adjoining the home. It will produce good crops for eight or ten years, yet from the time the farmer must wait till the crop attains its perfection, and from the care requisite to keep it from grass and weeds, we do not think it ever likely to come into general culture. The Highland Society have lately offered premiums for the culture of this plant in Scotland, and crops have been produced in dry sandy soils in the neighbourhood of Edinburgh; the climate, however, and the alternate and convertible system of culture scarcely practiced in the northern parts of the island, and which seems so well adapted to its agricultural circumstances, forbid the hope that it can ever become general.

5576. There are no varieties of the lucern deserving the notice of a cultivator

5577. What is called the yellow lucerne is the *Medicago fabalis* (*Lucerne en fausse*, or *Lucerne de Soide*, Fr. &c. 778.), a much harder and coarser plant, common in several parts of England, but not cultivated any where except in some poor soils in France and Switzerland.

776

5578. *Medicago maculata* and *medicula* are cultivated in France, but to a very limited extent on poor soils. *M. lupulina* (*lupuline*, or *lucerne d'or*, Fr.) resembles our well known hop trefoil, black (from its seeds) somewhat, or yellow clover; but it is seldom cultivated in Britain.

5579. The soil for lucern must be dry friable, inclining to sand, and with a subsoil equal to it in goodness. Unless the subsoil be good and deep, it is in vain to attempt to cultivate lucern. According to Young the soils that suit lucern are all those that are at once dry and rich. If says he, they possess these two criteria, there is no fear but they will produce large crops of lucern. A friable deep sandy loam on a chalk or white dry marly bottom is excellent for it. Deep putrid sand & ar on a dry basis, good sandy loam on chalk dry marl or gravel, all do well and in a word, all soils that are good enough for wheat, and dry enough for turneps to be fed on the land, do well for lucern. If deficient in fertility they may be made up by manuring,

but he never yet met with any land too rich for it.

5580. The preparation of the soil consists in deep ploughing and minute pulverisation; and, in our opinion, the shortest way to effect this, is to trench it over by the spade to two or three feet in depth, burying a good coat of manure in the middle or at least one foot from the surface. This is the practice in Guernsey where lucern is highly prized.

5581. The climate for lucern, as we have already hinted, must be warm and dry. It has been grown in Scotland and Ireland, and might probably do well in the southern counties of the latter country but in the former it has not been found to answer the commendations of its admirers.

5582. The season most proper for sowing lucern is as early as practicable in the spring months, as in this way the plants may be fully established before the season becomes too hot. The latter end of March for the more southern districts, may be the most proper period and the beginning of the following month for those of the north. When sown late, there is more danger of the plants being destroyed by the fly as it has been observed by Tuill. If the plants are intended to be transplanted out in the garden method, it will also be the best practice to sow the seed bed as early in the spring as the frosts will admit, in order that they may be strong, and fit to set out about the beginning of August.

5583. The manner of sowing lucern is either broad-cast or in drills, and either with or without an accompanying crop of corn for the first year. Broad-cast, with a very thin crop of barley or other spring corn, is generally, and in our opinion very properly preferred. Arthur Young, who has treated largely on this plant, observes, that "the greatest success by it that has been known is by the broad-cast method, which is nearly universal among the best lucern farmers, even among men who practice and admire the drill husbandry in many other articles. But as they mostly not all depend on severe harrowing for keeping their crops clean, which is a troublesome and expensive operation, he still ventures to recommend drilling; but very different drilling from that which has been almost universally practiced viz. at distances of eighteen inches or two feet. Objections to these wide intervals are numerous. If kept clean hoed, the lucern hides up so much dirt, being beaten to the earth by rain &c. that it is unwholesome, and the plants spread as into these spaces, that it must be reaped with a hook which is a great and useless expense. For these reasons, as well as for superfluity of crop, he recommends drilling at nine inches, which in point of freedom, mowing, and freedom from dirt, is the same as broad-cast, and another advantage is, that it admits scarifying once a year, which is much more powerful and effective than any harrowing. These facts are sufficient to weigh so much with any reasonable man, as to induce him to adopt this mode of drilling, as better to broad-cast by far than it is to drill at eighteen to twenty-four inches, which open to a quite different system, and a set of very different evils. Nine-inch rows might practically but not literally be considered as broad-cast, but with the power of scarifying. And in regard to the material point, of with or without corn, two considerations, he says, present themselves. One: the extreme liability of lucern to be eaten by the fly which does great mischief to many crops when very young, and against which the growing of corn is some protection. The value of the barley or oats is another object not to be forgotten. It is also pointed to the first year's growth of the lucern, which is very poorly productive even if no corn be sown; so that he must own himself clearly an advocate for drilling in among corn, either between the rows of nine-inch barley or across drilled barley, at a foot, if perhaps the latter is the best method, as there is less probability of the crop being laid to the damage of the lucern. The quantity of seed-corn should also be small, proportioned to the richness of the land, from one bushel to a bushel and a half according to the fertility of the soil; another caution against the mischief of lodging. If these precautions are taken, it would be presumptuous to say that success would follow, that being always, and in all things, in other words than corn; and may prove bad, the fly may eat and drought prevent vegetation; but having such circumstances, the farmer may rest satisfied that he has done what can be done, and if he do better, the advantage will be unquestionable."

5584. The quantity of seed, when the broad-cast method is adopted, is said to be from fifteen to twenty pounds per acre, and from eight to twelve if drilled. The seed is paler, larger and denser than that of clover; it is generally imported from Holland, and great care should be had to procure it plump and perfectly new, as two-years-

old seed does not come up freely The same depth of covering as for clover will answer

5585 *Lucern may be transplanted*, and when the soil is very rich and deep, it is said to produce very large plants; but such plants, from the bulk of their stools, are not likely to be so durable as those of a less size, and on the whole, for this reason and others relative to expense, the plan of transplanting does not seem advisable unless for filling up blanks.

5586 *The after-culture of lucern*, sown broad-cast, consists in harrowing to destroy grass and other weeds rolling, after the harrowing to smooth the soil for the scythe; and such occasional top-dressings of manure as the state of the plants may seem to require.

5587 *When lucern is drilled*, horse-hoeing may be substituted for harrowing, which, as already observed, is the only advantage of that mode of sowing The harrowing may commence the second year, and the weeds collected should always be carefully removed light harrows may be used at first, and in two or three years such as are heavier In succeeding years two harrowings may be required, one early in the spring, and the other at the close of the summer For these, and especially the last, Arthur Young recommends the use of a harrow of weight sufficient for four horses, and which does not cover a breadth of more than four feet. The mode of hoeing either by the hand or horse-hoe, or of stirring by the drill harrow requires no description.

5588 *The top-dressings given to lucern* may be either of the saline or mixed manures. Ashes are greatly esteemed, and also gypsum and liquid manure of any kind. Arthur Young advises to apply dung in the quantity of about twenty tons to the acre, every five or six years. Kent, however, thinks it a better practice to put a slight coat on annually in the spring season. Some recommend a slight top-dressing sown by hand every spring The farmer will in this, as in every case exercise his own judgment, and be guided by the wants of the plants, the return they yield for the expense bestowed on them, and the equable distribution of manure among his other crops.

5589 *The taking of lucern by mowing for soiling*, or hay or by ethering hurdling, or pasturing may be considered the same as for clover Lucern frequently attains a sufficient growth for the scythe, towards the end of April, or beginning of the following month and, in soils that are favourable for its culture, will be in a state of readiness for a second cutting in the course of a month or six weeks longer, being capable of undergoing the same operation, at nearly similar distances of time, during the whole of the summer season. In this last sort of soil with proper management, in the drill method, it has been found to rise to the height of a foot and a half in about thirty or forty days, affording five full cuttings in the summer But in the broad-cast crops, in the opinion of some, there are seldom so many cuttings afforded in the season, three or four being more common, as the growth is supposed to be less rapid than by either of the other modes.

5590 *The application of lucern* is also the same as that of clover The principal and most advantageous practice is that of soiling horses, neat cattle, and hogs but as a dry fodder it is also capable of affording much assistance and, as an early food for ewes and lambs, may be of great value in particular cases. All agree in extolling it as food for cows, whether in a green or dried state. It is said to be much superior to clover, both in increasing the milk and butter and improving its flavour In its use in a green state, care is necessary not to give the animals too much at a time, especially when it is moist, as they may be hoven or blown with it, in the same way as with clover and other green food of luxuriant growth.

5591 *The produce of lucern*, cut three times in a season, has been stated at from three to five and even eight tons per acre In soiling one acre is sufficient for three or four cows during the soiling season and a quarter of an acre, if the soil be good, or half an acre on a moderate soil, for all sorts of large stock, for the same period. Say however that the produce is equal in bulk and value to a full crop of red clover then if continued yearly for nine or ten years (its ordinary duration in a productive state), at an annual expense of harrowing and rolling, and a triennial expense of top-dressing it will be of sufficient value to induce farmers, who have suitable soils and climates, to lay down a few acres under this crop near their homesteads.

5592 *The nutritive product of lucern*, according to Sir H. Davy, is  $2\frac{1}{2}$  per cent., and is to that of the clovers and sainfoin as 23 to 39 This result does not very well agree with the superior nutritive powers attributed to lucern.

5593 *To sow seed*, the lucern may be treated precisely as the red clover and it is much more easily threshed, the grains being contained in small pods, which easily separate under the flail, or a threshing machine, or clover mill.

5594 *The diseases of lucern* appear to be the same as those of clover In Kent, blight and the slug are its greatest enemies.

Secs. III. *Saintfoin*. — *Hedysarum Onobrychis* L., *Diadelpsis Derdendria* L., and *Lagumichia* J. *Douglasia*, or *Eparcetta*, Fr., *Eparcetta*, Ger. *Cedrengola*, Ital., and *Eparcetta*, Span. (fig. 777)

5595. *Saintfoin* is a deep-rooting perennial with branching spreading stems, compound leaves, and showy red flowers. It is a native of England and many parts of Europe, but never found except on dry, warm, chalky soils, where it is of great duration. It has been long cultivated in France and other parts of the Continent, and as an agricultural plant was introduced from France to England about the middle of the seventeenth century. It has since been a good deal cultivated in the chalky districts and its peculiar value is, that it may be grown on soils unfit for being constantly under tillage, and which would yield little under grass. This is owing to the long and descending roots of the *saintfoin*, which will penetrate and thrive in the fissures of rocky and chalky understrata. Its herbage is said to be equally suited for pasturage and for hay and that eaten green it is not apt to swell or bloat cattle like the clovers or lucern. Arthur Young says, that upon soils proper for this grass no farmer can sow too much of it and in *The Code of Agriculture* it is said to be "one of the most valuable herbage

plants we owe to the bounty of Providence.

5596. There are no varieties of the *saintfoin* in England, but many other species of the same numerous family might be cultivated, such, for example, as the French *booev* suckle, a biennial that might be substituted for red clover on rich soils. The French have a variety which they call *Saintfoin à deux coupes*, and they also cultivated the *Saintfoin d'Espagne* or *Sulla*.

5597. The best soil for this plant is that which is dry, deep, and calcareous, but it will grow on any soil that has a dry subsoil. Kent thinks that the soils most suited to the culture of this sort of grass are of the chalky loam, and light sandy or gravelly kinds, or almost any of those of a mixed quality provided they are sufficiently dry, and have a rocky or hard calcareous bottom to check the roots at the depth of a foot or fifteen inches below the surface, which he conceives necessary as the plants are apt to exhaust themselves in running down and for this reason he considers it improper for being sown where there is great depth of mould or soil. It is a plant that is asserted by Marshall to afford a large produce even on those soils which are of the poorest quality, and on such as are of a more rich and friable nature to frequently produce abundant crops. Still, he conceives, that it is only in the calcareous soils, as the dry chalk and limestone, or such as have been well impregnated with that sort of matter, that it succeeds in a perfect manner or becomes durable. The advantages resulting from growing this plant on sandy soils in Norfolk have been already stated. (4744)

5598. The best preparation which any soil fit for this plant can undergo is, unquestionably trenching and we have little doubt that in most cases, all things considered, it would be found the cheapest. The usual preparatory culture, however, is the same as for clover: ploughing more deeply than ordinary either by means of the trench plough or what is better because more simple, by the common plough going twice in the same track. Boys (*Communications to the Board of Agriculture* vol. II.) recommends as a preparation for *saintfoin* 1st year pare and burn for turnips, to be eaten on the land by sheep, with the aid of some fodder 2d, barley to be sown very early with clover seed 3d, clover eaten off by sheep; 4th, wheat, 5th, turnips with manure, and 6th barley with *saintfoin*. The corn crops must be carefully weeded, and in particular cleared of charlock. Under this system, the produce has been great, and the ground has been laid down in the highest order with *saintfoin*, or any other grass calculated for this species of soil.

5599. With respect to the season of sowing *saintfoin*, it may be observed, that the earlier it can be put into the soil in the spring the better, as from the greater moisture of such soils there will be a greater probability of its vegetating in a perfect manner. Where the sowing is executed at a late period, and dry weather succeeds, Bannister thinks that much of the seed is prevented from growing, and that the young plants are more exposed to destruction from the fly, therefore, according to this writer, the sowing of *saintfoin* seed ought never to be deferred longer than the beginning of March, and it is still better to complete this work in February. Some, however, suppose it may be deferred to the middle of March without injury, and this is soon enough if it is to be sown with barley.

5600. The manner of sowing is generally broadcast; but it may be sown in drills and even transplanted, though neither of these modes can be recommended. Some advise its being sown with about half the quantity of barley usually sown for a full crop, which may shade and keep it moist during the first summer and at the same time not injure it from the crop being lighter, which is sometimes the case. Where the barley is drilled, the *saintfoin* may afterwards be put in, in the same manner, but in a contrary direction. If sown over the wheat, it should be harrowed in, and afterwards rolled. In whatever method it is sown, as the seeds are larger than those of many other herbage plants, they should be covered in with more care, and to a somewhat greater depth. By some the ploughing of the seed in with a very thin or shallow

sifted is recommended. In most cases, especially in all the more light sorts of land in which this sort of crop is grown, the use of the roller may be necessary immediately after the seed is put into the ground. It is the practice in some districts to sow a small portion of clover seed with saintfoin, with the idea of increasing the first year's produce; but as plants of different kinds seldom sown well when grown together from there being a continual contest in their growth for an secondary it is perhaps a better method to increase the proportion of the seed, without mixing it with that of other sorts. It is, however, supposed by Marshall that such a practice is beneficial in ultimately procuring a fine clean crop of saintfoin upon the land. It is a sort of crop that grows in so perfect a manner in the broad-cast method, that there can seldom be any necessity for having recourse to the drill. It may however be cultivated in the latter mode with much success and in Norfolk, it is the practice with some cultivators to have it drilled at nine inches across the barley crops which have been sown in the same way.

5601. *The quantity of seed in the broad-cast method, which is that mostly employed, is about four bushels the acre, though less is frequently given; but on such soils as are proper for this plant it is always necessary to have a full proportion of seed. By some however a much smaller quantity is made use of, and where the drill system is had recourse to, a still smaller proportion is used, as from two to two and a half or three bushels. It has been observed, that in Lincolnshire where this plant is much grown, "the common allowance of seed is five bushels to an acre, and that a gentleman south of Lincoln advises the sowing a small quantity of trefoil with it (about four pounds on an acre). The reason for this is, that in that exposed country the young plants suffer more by the sun in summer than by the frost in winter. Of course the trefoil coming to perfection the first year and living only three, will be a shelter for the young plants during the first year or two, and die off when the saintfoin wants its room.*

5602. *In the choice of the seed the safest practice for the cultivator is to select it from the best and most abiding plants in this particular soil, as that purchased from the seed-shops can rarely be depended upon. A certain method of knowing the goodness of the seed is, by sowing a number of the seeds, and seeing how many plants are produced by them. But the external signs of the seeds being good are, that the husk is of a bright colour and the kernel plump, of a light grey or blue colour and sometimes of a shining black. The seed may be good though the husk be black as that is owing sometimes to letting it receive wet in the field and not to its being half-rotten in the heap. If the kernel on being cut across appears greenish and fresh, it is a certain sign that it is good but if it is of a yellowish colour and friable, and looks thin and pitted, it is a bad sign. Others observe that the best seed is plump, heavy bright, and of a yellowish red colour, and that it should always be sown while quite fresh, as old seed, or seed that has been long kept never vegetates in a perfect manner. Seed of this sort is in general from about three to five shillings the bushel.*

5603. *The after-culture and management of saintfoin consists in occasional dressings with manure, and, in the judicious intervention of mowing and pasturing*

5604. *Some farmers do not mow in the first year while others do but in the second year and in the succeeding summers, a crop of hay may be taken and the after-grass fed down with any sort of stock but sheep, till towards December. These should not be permitted to eat it too close as, from the largeness of the roots, they might by so doing injure the crowns of the plants. In the following autumn there will, however be less risk in this respect, and sheep as well as cattle stock may be turned in and kept upon the pastures till they are well eaten down being always careful to shut them up as early as possible in the beginning of the year. This is the opinion of Kent. As this sort of herbage is thought to be improved in its taste by being tipped by the frost it may be a proper practice not to turn stock upon these leys too early in the autumnal season perhaps not before the latter end of September when this sort of rotten or after grass will be found to be a much effect in promoting the flow of milk in cows, as well as in forwarding the condition of fattening beasts great store of feed being still left for sheep. But with this sort of stock they should not be too closely fed down nor should the sheep remain too long upon them. It has been suggested that all sorts of cattle stock should be removed by the beginning of the year from these roughs, as much harm might be done by their continuing longer.*

5605. *In top-dressing saintfoin peat-shales are the best material that can be made use of where they can be procured in sufficient quantity and other sorts of shales are likewise found beneficial where these cannot be had. They should be applied so as to form a thin, even, regular dressing over the whole surface of the crop. In this view soot has also been found of great utility when spread evenly over such leys about the beginning of January in the proportion of about twenty-five or thirty bushels to the statute acre and manure has been employed in the same way with great success and advantage, as shown by Rammeter in his *Synopsis of Husbandry*. It is supposed that where these sorts of top-dressings can be applied every third or fourth year the saintfoin crops, when well established in the soil, may be preserved in a state of vigorous growth for ten or fifteen years, or more, and the land be considerably improved by the roots striking so deeply into it.*

5606. *In taking and using the saintfoin crop, the same practices may be followed as in taking clover it may be mown for soiling, hay, or seed, and eaten on the spot by tethering, hurdling, or common pasturing.*

5607. *In making it into hay It is cut immediately on its coming into full blossom, and as it remains but a short time in this state, as much expedition as possible should be employed both in mowing and making the produce into hay. It is remarked by the author of *The Synopsis of Husbandry* who resides in a district where the culture of saintfoin is frequent, that of all other hay plants it requires the least pains in making. When the season is favourable, the hay makers may follow the scythe, and having turned over the swaths, throw them into wind-rows the succeeding day after the crop is mown, when it may be immediately formed into cocks, and the whole crop be fit for carting in a week, sometimes in three days after it is mown. Though it may appear very green, and the stack when made take on or acquire a considerable degree of heat, there is no danger to be apprehended, provided the weather has been fair during the hay making as it is so far from taking harm by heating in the stack, that the contrary state is the most to be feared. For this reason great care is necessary not to suffer the fodder to continue long either in the swath or in cocks, lest the sun and wind should dry it up too fast, and by exhaling its juices prevent the heating in the stack, and thereby render it of little value. In order to preserve its succulence, in some places they put a number of these cocks together so as to form large cocks of a size to contain a load in each and they finish the stacks out of the cocks. It is likewise a practice with many farmers, where the crop is slight, to turn the swaths, and then run them into cocks with a three-pronged barley fork following with a wooden draw-rake, the head of which is of sufficient width to cover the ground occupied by three or four swaths, in this manner proceeding with the utmost despatch and saving a deal of labour and expense in the business.*

5608. *In regard to the frequency of cutting saintfoin It is probable that on the thinner sorts of soils it can seldom be done more than once; but on those of the deeper sorts two crops may sometimes be taken, in the same manner as with clover care being taken in these cases that the future growth of the plants be not injured by this means.*

5609. *The usual duration of saintfoin, in a profitable state, is from eight to ten years. It attains its perfect growth in about three years, and begins to decline towards the eighth*

or tenth on calcareous soils, and about the seventh and eighth on gravels. There are instances, however, of fields of sainfoin, which had been neglected and left to run into pasture, in which plants have been found upwards of fifty years from the time of sowing. It has been cultivated upwards of a century on the Cotswold Hills, and there roots of it have been traced down into stone quarries from ten to twenty feet in length, and in Germany Von Thier found them attain the length of sixteen feet. In general the great enemy to the endurance of sainfoin is the grass, which accumulates and forms a close turf on the surface, and thus chokes up the plant.

5610. *The quantity of produce in the state of hay on a medium of soils and cultivation, may probably be estimated at from about one and a half to two tons the acre, and on the poorer and thinner staple sorts of land it will, perhaps, seldom afford less than from a ton to a ton and a half on the acre*

5611 *The nutritive products of sainfoin are the same as clover viz. 3 $\frac{1}{2}$  being 1 $\frac{1}{2}$  per cent more than those of lucern.*

5612. *In sowing seed from sainfoin it should remain on the land till the husks become of a somewhat brownish colour and the seeds are perfectly plump and firm as by these means they will not only be better in their quality but be in less danger of being injured in the field, from the very short time that it will be necessary for them to remain, and also less in danger of being hurt by heating when laid up for future use. It has been stated, that it requires some experience to know of what degree of ripeness it is best to cut the seeded sainfoin, because all its seeds do not ripen at the same time. Some ears blossom before others and every ear begins to blossom at its lower part, and continues to blow gradually upwards for many days so that before the flower is gone off at the top the seeds are almost mature at the bottom. From this cause, if the cutting be deferred till the top-seeds are quite ripe, the lower, which are the best, would shed and be lost.*

5613. *The best time to cut it is when the greater part of the seed is well filled the first blown ripe and the last blown beginning to be full. The unripe seeds will ripen after cutting, and be in all respects as good as those that were ripe before. Some for want of observing this, have suffered their sainfoin seed to stand till all of it has shed and been lost in cutting. Sainfoin should never be cut in the heat of the day while the sun shines out, for then much even of the unripe seed will shed in mowing. The right time for this work is the morning or evening, when the dew has rendered the plants supple. When the weather is fine and clear the sainfoin will soon dry sufficiently in the swaths without turning them, but if any rain has fallen, and there is a necessity for turning them, it should be done very gently while they are moist, and not with two swaths together as in hay made of sainfoin before it has seeded. If the swaths are turned with the handle of the rake it is best to raise up the ear-side first, and let the stub-side rest on the ground in turning; but if it is done with the teeth of the rake let the stub-side be lifted up, and the ears rested on the earth. If it be cocked at all the sooner it is done the better because if the swaths are dry, much of the seed will be lost in separating them, the ears being entangled together. When moist, the seeds stick fast in the ear, but when dry they drop out with the least touch or shaking. It is, however, the best practice, as soon as the proper degree of maturity has been attained by the crop, to mow it in as short a time as possible and let it remain exposed in the swath until the upper surface is fully dried, when it must be wholly turned over but in a very careful manner so as to prevent the seeds from shedding and being lost. When this side has been rendered perfectly dry and crisp in the same way as the other the crop should either be threshed out upon cloths in the field where it is grown or laid up in stacks to be afterwards threshed when the farmer has more leisure and convenience for the work.*

5614. *The work of threshing out the seeds in this kind of crop is much less troublesome and expensive than in the clover kind. In cases where threshing machines are in use, the business may be executed by them with great ease and facility. It has, however, been observed by a late writer that when the season is favourable, the practice of threshing it out in the field is probably the most beneficial, as the stems or haulm may be laid up for the purpose of fodder in the stack."*

5615. *As the threshing in the field cannot be done but in very fine weather and while the sun shines in the middle of the day the best manner of performing it is to have a large sheet pegged down to the ground, for two men to thresh on with their flails, while two others bring them fresh supplies in a smaller sheet, and two more clear away the hay that has been threshed. The seed is emptied out of the larger sheet, and riddled through a large sieve to separate it from the chaff and broken stalks after which it is put into sacks, and carried into the barn to be winnowed. Care should be taken not to let the hay get wet, as in that case it would be spoiled. It is a very important, but difficult matter to keep the seed that has been threshed in the field from becoming wet. If it be winnowed immediately and laid in a heap or put into a sack, it will ferment to such a degree in a few days that the greater part of it will lose its vegetative quality. During that fermentation it will be very hot, and small sour spreading it upon a barn-floor though but seven or eight inches thick will answer no end, unless it be frequently and regularly turned until the heating is over but even this will not make its colour keep so bright as if it were well housed, well dried and threshed in the winter. Laid up unthreshed it will keep without any danger of spoiling, because it does not lie close enough to heat. The best way to preserve the seed threshed in the field is to place a layer of straw upon a barn-floor and upon that a thin layer of seed, then another layer of straw, and another layer of seed and so on. By this means the seed mixing with the straw will be kept well, and come out in the spring in as fresh colour as when it was put in.*

5616. *In respect to the produce in seed, it is said to be usually "from about four to five sacks in some districts, but in others it will probably be much less, especially on the shallower sorts of sainfoin soils." But this must obviously be liable to great variation from seasons, &c.*

5617 *The diseases of sainfoin are few, there being little danger of failure after it has escaped the fly, which attacks the clover tribe in germinating.*

SECT IV Various Plants (not Gramineæ) which are or may be cultivated as Herbage and for Hay

\*5618. Among the inferior-herbage plants which are occasionally cultivated, are burnet, ribwort, furze, and spurry. Those which might be cultivated are very numerous, and includes several species of *Vicia*, *Lathyrus*, *Gallega*, *Lotus*, *Trifolium*, *Medicago*, and others of the native Leguminosæ, or pea-like flowering plants, and *Achillea*, *Achermilla*, *Chenanthus*, *Sparganium*, *Ajium*, and a variety of others of different families. With the exception of the chicory and furze, there are none of these plants that deserve the attention of the professional farmer: ribwort and burnet are occasionally sown but they are of little value as hay plants and in most pastures their place might be more advantageously occupied by one or other of the natural grasses. With respect to the other plants enumerated, they have never been tried but by way of experiment, and are only mentioned as resources under peculiar circumstances, and as a field of enquiry and exertion for the amateur cultivator.

5619. The burnet (*Pimpinella grande* Fr. *Potiron sanguisorba* L. fig. 778) is a native plant, a hardy perennial with compound leaves, blood coloured flowers and a long tap-root. It was originally brought into notice by Roque, a commercial gardener at Walham green, near London who found means to procure the patronage of the Dublin and other societies to this plant, which being a novelty attracted the attention and called forth the eulogies of Arthur Young and other leading agriculturists of the day. Miller however, at the time observed, that whoever will give themselves the trouble to examine the grounds where it naturally grows, will find the plants left uncut by the cattle, when the grass about them has been cropped to the roots besides in wet winters and on strong land the plants are of short duration and therefore very unfit for the purpose of pasture or hay: nor is the produce sufficient to tempt any persons of skill to engage in its culture.

5620. Curtis says of burnet, that it is one of those plants which it has for some years past been attempted to introduce into agriculture but not answering the farmer's expectation, it is now in a great degree laid aside. Cattle are said not to be fond of it: nor is its produce sufficient to answer the expense attending its culture. It is to be lamented that persons do not pay a little attention to the nature of plants before they so warmly recommend them. A small plant, scarcely ever met with but on hilly and chalky ground and to which cattle in such situations do not show any particular attachment is not likely to afford better or more copious nourishment than the clovers and other plants already in use.

5621. According to Boys in *The Agricultural Survey of Kent*, it affords herbage in the winter and spring months, but is not much liked either by cattle or sheep.

5622. Dr. Anderson reports that burnet retains its verdure pretty well during the winter months, but affords such scanty crops as hardly to be worth the attention of the farmer.

5623. A correspondent in the *Museum Rusticum*, a work very favourable to burnet, confesses with reluctance that it is not deserving of any exalted character but rather the contrary and that it is in no degree to be compared to the common clover which is cultivated at half the expense. It appears from some accounts that horses will not eat it at all and that it is frequently will not take it without great reluctance. Its slow growth is also made a great objection being only about five inches high and having scarcely one head in flower whilst lucern on the same soil sown the same day and much thicker was eighteen or twenty inches in height. It is not meant by this, however to discourage that laudable spirit of improvement which so happily prevails at present but to caution such as introduce any new plant to make themselves well acquainted with its natural history.

5624. Those who wish to cultivate burnet as an herbage and hay plant, may treat it exactly as directed for sainfoin as a pasture plant it is sown among the grasses in the same way as white or yellow clover. A bushel of seed is commonly sown to an acre.

5625. The ribwort plantain (*Plantago lanceolata* L. fig. 779) is a hardy native with a tuft of long ribbed leaves springing from the crown of the root, long naked flower stems and a long moniliform tap-root. It abounds in dry soils, as do several other species of plantain, especially the *P. media*. On dry soils it affords little herbage, and is often left untouched by cattle. Curtis, Withering and other British botanists, speak unfavourably of the ribwort as a pasture herb but Haller attributes the richness of the milk in the Swiss dairies to the favour of this plant, and that of the *Achermilla*, in the mountain pastures. In rich moist or watered lands its herbage is more abundant, and its flavour altered, — a circumstance not uncommon in the vegetable kingdom but from which it does not always follow that the plant so altered is deserving of culture. In conformity with this observation, though the ribwort is a scanty and rejected herbage on poor dry soils it is said by Zeppa of Milan to grow spontaneously in every meadow of Lombardy especially in those which are irrigated. It vegetates early flowers at the beginning of May, ripens in five weeks, and is cut with the *Poa trivialis* the height of the leaves is about one foot, and of the stalk a foot and a half. It multiplies itself much by the seed, and a little by the roots, which it continues for some time to reproduce. Ribwort, more especially in a cultivated state is eaten heartily by every sort of cattle and in particular by cows, who like it most in May when it has great influence on the milk, as the hay has on the stomach. In Scotland it is a useful addition to the proper grasses on lands to be pastured by sheep at the rate of two or three head to the acre. Where kept well fed down by stock, there can be no doubt of its being a very good and nourishing pasturage plant for both cattle and sheep but it is by no means adapted for hay or soiling.

5626. Young says, that he had long before recommended this plant for laying land to grass, and sowed it on his own farm. At the same time he thinks it extravagant to propose demodion and sorrel as plants

proper for a cow pasture, and conjectures that those plants, being found among good ones, have qualities given them which do not properly belong to them. He is likewise inclined to make the same conjecture in respect to narrow-leaved plantain, ribwort, or rib-grass, and should even have preferred dandelion and sorrel to it: but he is conscious of opposing theory to practice.

5027. Dr. Anderson states, that narrow-leaved plantain or rib-grass is well liked by horses and cattle, and yields a very good crop upon rich ground tending to dampness, if it is at the same time soft and spongy: but that upon any soil which has a tendency to bind, or upon dry ground it furnishes a very scanty crop. It has been made use of in some parts of Yorkshire as a summer grass. As an article of pasture for cattle and sheep, it is there on high esteem. It is not, however, well eaten by horses. As an article of hay it is held to be detrimental to the crop; retaining it up an unusual length of time, and when fully dry falling into a small compass, or being broken into fragments and left belied in the field.

5028. The culture of the plantain is the same as that of clover; its seed is about the same size, and consequently the same proportion of it will sow an acre.

5029. The *whale, furze, or gorse* (*Ajace Juno maris, Genet deborac* Fr. *Ulex europæa* L., Ag. 780), is a well known shrub, found wild on dry light soils, and in rather hilly situations, in the warmer and more temperate parts of Europe, but not in Sweden, or in Russia or Poland, north of Moscow and Casan. It has been known as a nourishing food for cattle from a very early period, and has been sown in some parts of England for that purpose and for fuel. Dr. Anderson knows few plants that deserve the attention of the farmer more than the whin. Horses are peculiarly fond of it: so much so, that some persons think they may be made to perform hard work upon it, without any feeding of grain: but he thinks it tends more to fatten a horse than to fit him for hard labour: and that therefore some grain should be given with it where the work is severe. Cattle, he says, eat it perfectly well when thoroughly bruised, and grow as fat upon it as upon turnips; but unless it be very well bruised for them, they will not eat it freely and the farmer will be disappointed in his expectations. It has lately been found excellent food for horses in the Highlands of Scotland. (*Edinb. Soc. Trans.* vol. v.) Cows suck upon it youth nearly as much milk as whin or upon grass: it is free from any bad taste. The best winter-made butter he ever saw was obtained from the milk of a cow fed upon this plant. This food should be made use of soon after being prepared. Two bushels, with a proper allowance of hay, have been found to be sufficient for a day for three horses performing the same labour as with corn. It also seemed useful to horses labouring under broken wind and grass. Poor hungry gravelly soils, which would not have let for five shillings

780

an acre, have been rendered worth twenty shillings by sowing them with *Artemisida*, in places where fuel has been scarce: the furze being frequently used for heating stoves, burning lime and bricks, and also for drying malt: but it is not worth cultivating in countries where fuel of any kind is cheap, or upon such lands as will produce good grass, corn, or other crops employed as the food of animals.

5030. The culture of the whin is thus given by the same author:—A field of a good dry loamy land, being well prepared, be sowed, along with a crop of barley, the seeds of the whin in the same way as clover is usually sown, all sowing at the rate of from fifteen to thirty pounds of seed to the acre. The seeds, if harrowed in and rolled with the barley, quickly spring up, and advance under the shelter of the barley during the summer and keep alive during the winter. Next season if the field has not a great tendency to run to grass so as to choke them, they advance rapidly after midsummer, so as to produce a pretty full crop before winter. This you may begin to cut with a scythe immediately after your clover fails, and continue to cut it as wanted during the whole of the winter: but it is supposed that after the month of February the taste of this plant alters, as it is in general believed that after that time horses and cattle are no longer fond of it. He, however, observes, that never having had a deficiency of whins to serve longer than towards the middle of February or beginning of March, he cannot assert the fact from his own experience. He has frequently seen horses feeding the whins with their heads so as to bruise the prickles, and then eating them, even in the months of April and May, and he says, that sheep which have been used to this food certainly pick off the blossoms and the young pods at that season, and probably the prickles also; so that it is possible the opinion may only be a vulgar error. This is, he thinks the best way of rearing whins as a crop for a winter food for cattle or horses. But for sheep, who take to this food very kindly when they have once been accustomed to it, less industry is required: for if the seeds be simply sown broad-cast, very thin (about a pound of seed per acre) upon the poorest soils, after they come up the sheep of themselves will crop the plants and soon bring them into round close bushes as the animal nibbles off the prickles one by one very quickly so as not to be hurt by them. Sheep, however, who have not been used to this mode of browsing do not know how to proceed, and often will not taste them; but a few that have been used to the food will, he observes, soon teach all the rest how to use it.

5031. Another very economical way of rearing whins, but which he has seen practised rather than experienced himself, is this:—Let a farm be enclosed by means of a ditch all round with a bank thrown up on one side, and if stones can be had, let the face of that bank be lined with the stones, from bottom to near the top, this being to slope backwards with an angle of about sixty or seventy degrees from the horizon. Any kind of stones, even round ones gathered from the land, will answer the purpose very well, upon the top of the bank sow whin-seeds pretty thick and throw a few of them along the face of the bank. Young plants will quickly appear. Let them grow for two years and then cut them down by means of a hedge-bill, sloping down by the face of the bank. This mode of cutting is very easy, and as the seeds soon inanimate themselves among the crannies of the stones, the whole face of the bank becomes a close hedge, whose shoots spring up with great luxuriance. If another ditch be made on the other side of the bank, and if this be managed in the same way and the hedge cut down only once every second year (and in this way it affords very good food for beasts), the inside and outside being cut down alternately the fence will at all times continue good, as the hedge at the top will at all times be complete. This mode of rearing whins is, he remarks, both convenient and economical. But where stones cannot be obtained for making the facing the bank very soon moulders down, and becomes unfit for the purposes of a fence. Circumstances have prevented him from ascertaining what is the weight of the crop that may be thus obtained, but he thinks he may safely venture to say that it is at least equal to that of a crop of green clover: and if it be considered, that this affords a green succulent food during winter on which cattle can be fed as well as on red grass in summer: it will, he thinks, be admitted, that it must be accounted even a more valuable crop than clover. After being cut, he also remarks, that it springs up the following season with greater vigour than before, and in this situation acquires a degree of health and succulence very different from what it is ever observed to possess in its natural state. He has seen shoots of one season near four feet in length. The prickles too are so soft, and the stems so tender, that very little bruising is necessary; indeed horses, that have been accustomed to this food, would eat it without any bruising at all; but fatted cattle, whose mouths seem to be more tender, always require it to be well bruised. How long crops of this sort may continue to be annually cut over without wearing out, he cannot say, but he believes a long while in favourable circumstances. One thing, however, it is necessary to attend to in

order to guard against its being destroyed as, during the beginning of the season, nature seems to be solely employed about the great work of fructification, and it is not till near Midsummer that the whin begins to push forth its wood-bearing branches, which advance with great luxuriance during the latter part of the season only it may happen, that if care be not taken to have the grass that springs up on the field, before the whin begins to send out its shoots, eaten close down, that grass will acquire such a luxuriance before the young branches of the whin begin to advance, as to overtop them, and choke them entirely. Whoever therefore, has a field under this particular crop, must be careful to advert to this circumstance, or, if the field be in good heart, he will infallibly lose it. The field therefore should be kept as

a pasture bare as possible during the beginning of the season, and the cattle should only be taken from it when the shoots of the whin begin to advance with vigour. Under this management, he presumes, it may be kept for many years, and yield full crops; but, unless the mowers be particularly attentive at the beginning, to cut it as low as possible, it will very soon become impossible to cut the field with a scythe, as the stumps will acquire so much strength as to break the scythe when it happens to touch them.

6632. The spurry (*Spergula* Fr. *Spergula arvensis* L., fig. 781) is a diminutive annual weed, on dry sandy corn-lands, in most parts of Europe. In Germany and the Netherlands, it is sown on the corn stubbles, and in the intervals of time that occur between some crops is fed with sheep. It may be sown and reaped in eight weeks, either in autumn or spring. It is said to enrich the milk of cows, so as to make it afford excellent butter, and the mutton fed on it is preferable to that fed on turnips. Hence spurry greedily and it is supposed to make them lay a great number of eggs. Whether in hay or cut green, or in pasture, Von Thier observes, it is the most nourishing in proportion to its bulk, of all forage, and gives the best flavoured milk and butter. It has been recommended to be cultivated in England. But it never pays the expense of seed and labour in this country, even on the poorest soil, or at all events, as Pro esser Martyn observes, we have many better plants for such soils.

6633. The common broom (*Genet* commun, Fr. *Spartium scoparium* L., fig. 782) is cultivated in the southern parts of France on the poorer sorts of soil, in the same way as hemp, for the purpose of stripping the bark from it, and converting it into a kind of thread. It is likewise cultivated in these places as a winter-food for sheep, and it is said they eat it with great avidity preferring it to many other plants. It is however liable to produce diseases of the urinary passages, by its diuretic qualities. It has been recommended by Young to be cultivated in England as food for sheep and horses, who are said to eat it after they get accustomed to it; also for sheath ropes become food for bees fuel, and burning on the spot to improve the soil. Its culture is the same as that of the whin but very peculiar, indeed, must be that situation where its culture is adapted for any of the above purposes. It is a useful protection of game in plantations, from which source abundance may be had for beehives. The Spanish broom (*S. panicum* L., fig. 783) might

be grown perhaps still more advantageously than the common species.

6834. The parsley (*Parsl* commun, Fr. *Apium Petroselinum* L., fig. 784) is a well known biennial with a large sweet tap-root. It is a native of Sicily but endures the British winter like a native plant. It is sown along with clover and grass seeds in some places, and especially in Lincolnshire, as a preventive of the rot in sheep. Fieet, of Hampshire, famous for curing the rot in sheep, cultivates it largely with success. He sows half a bushel to the acre, with a bushel of rye-grass with spring corn; and he finds that it lasts in the ground till it is permitted to seed. He feeds it constantly it being excellent for sheep, and when suffered to get a head wonderfully fed upon by pigs in the autumn. After September it will not, he says, run to seed. When it was ploughed up he obtained good oats. The land was poor and in the next round of the course the clover was much the better for the parsley having been sown or the clover omitted for in a field half parsley half clover when the clover came again to be sown, it was excellent on the parsley half, but bad on the clover part. In laying down land to grass, Hoyal, in the fourth volume of *Compendium in the Science of Agriculture*, advises the sowing with twelve pounds of white clover, two pounds of red clover, two pecks of rye-grass, and two pounds of parsley to the acre as the parsley stands two years, and by its diuretic qualities prevents the sheep from dying of the red-water, which too luxuriant clovers are apt to produce. In Scotland, also, it has been sown with success, and greedily eaten by horses, cows, and hogs. The seed requires a longer period to germinate than that of any other agricultural plant, and might probably be advantageously prepared by steeping and turning. It must be fresh, as two-year-old seed will not grow. It is easily procured by the pound or bushel, from the seedsmen

and as easily raised by letting a few drills in a garden shoot into *over-stems*.

6835. The *Spiraea Ulmaria* L. queen of the meadows, *Reine des Prés* Fr. the *Scabiosa arvensis*; the *Hesperis matronalis*; the *Centaurea Jacea*, are sown in France along with the parental grasses, and their seeds may be had in the French seed shops, but they cannot be recommended to soils and climates where any of the clovers or true grasses will thrive so as to form an abundant herbage.

6836. The wallflower (*Cheiranthus Cheiri* L.) is a well known garden flower and at the same time a native, and very hardy on dry soils. Like the parsley it is an antiseptic, and has been recommended to be cultivated for the same purposes, and in the same manner.

that in the greater part of North America, the sorts that grow naturally on the plains are almost all annuals, and consequently with the first frost they die, and the ground remains naked till a fresh crop rises from the self-sown seeds next spring. Nearly the same thing may be said of Poland and Russia, with the exception of the banks of rivers and the mountains.

5644. *The universal progress of the forage grasses and the rapidity with which all soils become covered with them when left uncultivated, are the obvious reasons why their systematic selection and culture are but of recent date.* Though the Romans cultivated clovers, and were careful of their meadows, it does not appear that the seeds of the proper grasses were collected and sown by them. None of the agricultural writers, from Peter of Bologna to Parkinson in 1646, say a word about sowing grasses, though they all mention clover and lucern. This branch of culture appears to have originated in England about the middle of the seventeenth century, and the grass made choice of was the rye-grass. The first mention made of it for cultivation is in Dr Plot's *Oxfordshire* printed in 1677. "They have lately sown" says he, "rye grass, or the *Græmen foliaceum*, by which they improve any cold, sour clay weeping ground, for which it is best, but good also for drier upland grounds, especially light stony or sandy land, which is unfit for sainfoin. It was first sown in the Chiltern parts of Oxfordshire, and since brought nearer Oxford by one Euxenes, an ingenious husbandman of Islip, who, though at first laughed at, has since been followed even by those very persons that scorned his experiment." The first grass tried after rye-grass appears to have been the *Phleum pratense*, by Roque of Waltham Green about 1700. Soon afterwards the seed of cock s-foot grass was introduced from Virginia, under the name of orchard-grass, by the Society of Arts. (*Ann. Mag.* 1708 141); fox-tail was tried at a later period, on the suggestions of Stillingfleet and Cusack.

5645. *Stillingfleet* about 1750, drew the attention of the reading agriculturist to the selection of different species of grasses, as did Dr Anderson about the same time, and *Bwyne* (*Græminæ Pæduncæ*) and *Curtis* (*Observations on British Grasses*) soon afterwards. The origin of this attention to grasses and native plants may be traced to the practice of forming local floras by botanists and especially to the *Flora Suedica* of Linnæus, and the *British Flora* of Hudson, Withering, Lightfoot, Smith, &c. in which the medical and economical properties of the plants were mentioned and, in imitation of Linnæus particular notes taken of the animals which fed upon them.

5646. *John Duke of Bedford* made the latest and most laborious efforts towards attaining a knowledge of the comparative value of all the British and some foreign grasses worth cultivating. The result is given in an appendix to Sir H. Davy's *Agricultural Chemistry*, and more at large in *Hooker's Herbarium Gramineum*. *Woburnensis* 3vo. 2d edit. 1825, a work which may truly be said to form an epoch in the department of agriculture, and which will probably long continue to be the ground-work of all that shall continue to be done in this branch of the subject.

"5647. With respect to the general culture of grasses, though no department of agriculture is more simple in the execution, yet from their nature considerable judgment is required in the design. Though grasses abound in every soil and situation, yet, all the species do not abound in every soil and situation indifferently. On the contrary no class of perfect plants is so absolute and unalterable in its choice in this respect. The creeping rooted and stoloniferous grasses will grow readily on most soils but the fibrous-rooted species, and especially the more delicate upland grasses, require particular attention as to the soil in which they are sown for in many soils they will either not come up at all, or die away in a few years and give way to the grasses which would naturally spring up in such a soil when left to a state of nature. Hence in sowing down lands for permanent pasture it is a good method to make choice of those grasses which thrive best in adjoining and similarly-circumstanced pastures for a part of the seed and to mix with these what are considered the very best kinds.

5648. *The most important feature in the culture of pasture grasses is mixture of sorts.* The husbandman, observes one of the most scientific agriculturists in Scotland, who clothes his fields only with rye-grass and clover employs a limited machinery the farmer being unproductive in summer, the latter moderately so in spring but when he for this purpose, uses a variety of plants differing in their habits of growth and periods of luxuriance a numerous and powerful machinery is kept successively in full operation. (*Quar Jour Ag* vol II p.247)

5649. *The effect of a mixture of grasses* may be accounted for from some species putting forth their foliage, and reaching a maximum of produce at different periods from other kinds. From some being gregarious or social, and others solitary and never producing a close turf by sowing seeds of several species together which are dissimilar in their habits of growth and arrive at a maximum of produce at different periods of summer and autumn there is secured throughout the season a succession of fresh herbage, rendered, by the erect and creeping foliage of the different species, so dense and abundant as greatly to surpass in quantity that obtained from the cultivation of two or three kinds only (*Ibid.* p.246.)

5650. *New and excellent varieties* of many of the grasses especially those used or fit to be used in the convertible husbandry might no doubt be obtained by selection and cross-breeding, and it is much to be wished that this were attempted by cultivators.

5651. *The grasses to be here treated of* may be classed as tall sorts, or those best fitted for hay and dwarf grasses, or those fit only for pasturage those experimented on at Woburn will next be noticed.

#### SECT I Tall-growing or Hay Grasses.

5652. *The hay grasses* for the purposes of agriculture may be advantageously divided into those of temporary, and those of permanent duration.

##### SUBSECT 1 Tall or Hay Grasses of temporary Duration.

"5653. *The most valuable of this duration* are the biennial, or, as it is commonly but erroneously called, the annual, perennial, and subperennial rye-grass (*fig* 789 a), the

cock 3-foot grass (b) and woolly soft grass (c). Where a crop of hay is desired within the year, it is necessary to resort to such grasses as are annuals in the strict sense of the word; and none can be better for this purpose than the common oat (*Avena sativa*), cut and made into hay when it comes into flower. Next in order may be mentioned the other cereal grasses and the annual varieties of *Brizonia* the latter, however are very coarse grasses, though prolific in culm.

5654 The *biennial* rye-grass (*Lolium perenne* var *biennis* L.) is well known as being universally sown, either with or without clover, among corn crops, with a view to one crop of hay in the succeeding season.

It attains a greater height, and produces a longer broader spike of flowers, than the perennial rye-grass, and the produce in hay is considered greater than that of any other annual grass, equally palatable to cattle. It prefers a rich loamy soil, but will grow on any surface whatever not rock or undecayed bog.

5655 The *perennial* rye-grass (*Lolium perenne* L. *forma suave*, Fr. *Dauwende Lolche*, Ger. and *Loligo suave* Ital.) differs from the other in being of somewhat smaller growth, and in abiding for several years, according to the variety and the soil and culture.

5656 Many consider this grass coarse benty and very exhausting to the soil; but, after all the experiments that have been made on the other grasses, none have been found to equal it in the course of mowing and pasturing for two three or seven years. It is sown in Italy, and especially in Lombardy, and also in France and Germany along with clover for the same purposes as in this country, and, as Von Thier has remarked, though some have tried other species, both in these countries and in England they have in the end returned to rye-grass. When intended as a pasture grass, if stocked hard, and when for hay if mown early the objections to it are removed. (Code of Agriculture.) G. Sinclair says the circumstance of its producing abundance of seed, which is easily collected, and vegetates freely on any soil its early perfection and abundant herbage the first year, which is much relished by cattle are the merits which have upheld it to the present day, and will probably for some time to come continue it a favourite grass among farmers. But the latter merit is inconsiderable, the plant impoverishes the soil in a high degree if not cut before the seed ripens. When this is neglected the field after autumn sowing exhibits only a brown surface of withered straw. Let the produce and nutritive powers of rye-grass be compared with those of the cock 3-foot grass, and it will be found inferior nearly in the proportion of 5 to 15 to meadow fix-tail of 15 and to meadow fescue of 5 to 17 (Hort. Gram. 1766 3d edit. 515, and see 5652.) In a subsequent page he observes, "The new varieties, however of this species of grass, which have been discovered of late years, remove in a considerable degree the serious object on which applied to the common rye-grass. (Id. 412.) The varieties alluded to are all perennial, and as under:

*Slender* rye-grass, common in dry impoverished pasture land.

*Compressed or broad* rye-grass, found in rich soils, long under grass, and chiefly in better parts, in cut-ways, &c. It has short broad spikes, crowded with spikelets at the top.

*Fancy* rye-grass, found in rich meadow lands, and introduced by Fungy a cultivator in the neighbourhood of Edinburgh; spike nearly upright, spikes shorter than in the compressed rye-grass, the stem furnished with long leaves, and the root leaves large and numerous. Sinclair considers this the most valuable variety of the rye-grass.

*Whitehead* rye-grass, introduced by G. Whitehead Esq.,

of Aute House, Lincolnshire, an eminent cultivator of the pasture grasses, who, in 1825 had 60 varieties of *Lolium perenne* under experiment.

*Wickham* rye grass, introduced by Rudolph of Hildersheim.

*Russell's* rye grass, first cultivated by the late B. Russell Esq. editor of *The Farmer's Journal*, from seed obtained of plant in rich soil sown and raised in Hildersheim by the Duke of Bedford.

*Claret house* or *Church* best-grass, an excellent variety of rye-grass, cultivated in some parts of Berkshire.

All the above, except the first two, are excellent varieties. Fungy's and Russell's are considered the best.

5657 The *proportional value* which the grass at the time of flowering bears to the grass at the time the seed is ripe, is as 10 to 11. The proportional value which the grass of the latter month bears to the grass at the time of flowering, is as 4 to 10; and to grass at the time the seed is ripe, as 4 to 11.

5658 The seed of perennial rye-grass is not to be distinguished from that of the annual variety. It may be collected by hand, in most parts of Britain from old pastures, and a considerable quantity is annually so procured in Kent and Sussex. It is also grown purposely for seed in England and Scotland. Formerly it was the practice for farmers to collect the seed which dropped from the hay used by their horses; but rye-grass, grown for hay is now cut, by all judicious farmers, when it is just coming into flower and therefore to collect the glumes or empty husks can be of no use as seed. It has also been a common practice, in regard to rye-grass, to let the mixed crop of that and clover stand till the seeds of the former have attained a considerable degree of ripeness, when it is cut down and made into hay, in the usual manner; and the seeds of the rye-grass are separated by the use of the flail, commonly before the hay is put into the stack-ribs. Sometimes, when but a small quantity is wanted, the hay is merely shaken well upon a cloth, when it is building in the stack-yard or afterwards in the stable-loft, before it is put into the horse's racks. But in all of these methods, in order to obtain good seed, the clover must remain uncut beyond the proper season; and it is thus materially injured in quality while the value of the rye-grass seed, in such a crop, is merely a secondary consideration.

5659 When seed is the principal object of the culture of rye-grass, it ought not to be mixed with clover at all, though it may be sown along with any of the kinds of corn, and treated the year after in every respect as a crop of corn; bound up in sheaves, built in stacks, threshed with the flail, and drawn by the winnowing-machine in the usual manner.

5660 The difficulty of distinguishing between the annual and perennial varieties of rye-grass has led to the practice, in some places, of cutting or pasturing the first year's crop, and taking a crop for seed the second year. If the growth of the rye-grass plants be close and vigorous the second year, there is reason to be satisfied that the seed is of the perennial variety; and though red clover was sown with the rye-grass, a great part of it disappears by that time, and forms but a small portion of the second year's cutting. (Rep. Soc. Brit. art. Agr.)

5661 *The cock's-foot grass* (*Dactylis glomerata* L., fig. 788 b) is an imperfect perennial, and grows naturally on dry sandy soils. This grass may be known by its coarse appearance, both of the leaf and spike, and also by its whitish green hue.

5662. *One writer says* he has cultivated it largely and to his satisfaction, on wet loams on a clay near bottom, upon which the finer grasses are apt to give way in a few years to the indigenous produce. It suffered to rise high, it is very coarse; but, fed close, is a very valuable sheep pasture. He has sown two bushels an acre, and 10 lbs. common red clover, and when the clover wears out, the grass fills the lands and abides well in it. It grows well in winter. It has been found highly useful as an early sheep feed. It is early hardy, and productive, but is a coarser plant than rye-grass, and requires even greater attention in regard to being cut soon, or fed close. It does best by itself, and the time of its ripening being different from that of clover it does not suit well to be mixed with that plant. The pasturage it affords is luxuriant, and particularly agreeable to sheep. It is cultivated to a great extent, and with astonishing success, at Holkham. The quantity of sheep kept upon it, summer and winter is quite surprising, and the land becomes renovated by lying two or three years under this grass and enriched by the manure derived from the sheep. A field, in the park at Woburn, was laid down in two equal parts, one part with rye-grass and white clover, and the other part with cock's-foot and red clover. From the spring till midsummer the sheep kept almost constantly on the rye-grass but after that time they left it, and adhered with equal constancy to the cock's-foot during the remainder of the season. In *The Code of Agriculture* (p. 297 3d edit.) it is stated, that Sinclair of Woburn considers "no grass so well suited for all purposes as cock's-foot," and in the second edition of the *History of the Woburns* it is observed, that if one species only is thought preferable to another in the alternate husbandry that species is the *Dactylis glomerata*, from its more numerous merits. But a certain supply of the most nutritious herbage throughout the season will be in vain looked for from any one species of grass, and can only be found where nature has provided it in a combination of many. None appear better fitted for mixing with *Dactylis* than *Phleum pratense* and *grætenum*, *Poa trivialis*, *Holcus avenaceus*, *Phleum pratense*, *Lolium perenne*, and white clover. "A combination thus formed, of three parts cock's-foot, and one part of these species just mentioned, will secure the most productive and nutritive pasture in alternation with grain crops, on soils of the best quality, and even on soils of an inferior nature, under the circumstances of unfavourable seasons, will afford nutritive herbage, when otherwise the land would have been comparatively devoid of it, if one species of grass only had been employed. (*Hort. Græm. Wob. 2d edit. 414*)

5663. *The proportional value* which the grass at the time of flowering bears to the grass at the time the seed is ripe, is as 5 to 7 nearly. The proportional value which the grass of the littermash bears to the grass at the time of flowering, is as 6 to 10, and to the grass at the time the seed is ripe, as 6 to 14. Sixty-four drachms of the straws at the time of flowering afford of nutritive matter 1½ dr. The leaves or littermash and the straws simply are therefore of equal proportional value; a circumstance which will point out this grass to be more valuable for permanent pasture than for hay. The above details prove, that a loss of nearly one third of the value of the crop is sustained, if left to the period when the seed is ripe, though the proportional value of the grass at that time is greater, i.e. as 7 to 5. The produce does not increase if the grass is left growing after the period of flowering, but uniformly decreases, and the loss of littermash (from the rapid growth of the foliage after the grass is cropped) is very considerable. These circumstances point out the necessity of keeping this grass closely cropped, either with the scythe or cattle, to reap the full benefit of its merits.

5664 *The woolly soft grass* (*Holcus lanatus* L., fig. 580 c) is an imperfect perennial, and rather late flowering grass of a short unsubstantial appearance, and found chiefly in poor dry soils. It is, however a very common grass, and grows on all soils, from the richest to the poorest. It affords abundance of seed, which is light, and easily dispersed by the wind.

5665 *It was cultivated at Woburn on a strong clayey loam*, and the proportional value which the grass at the time the seed is ripe, bears to the grass at the time of flowering, is as 11 to 12. Young of Essex observes of this grass, that it flourishes well on any moist soil, and should be sown chiefly with a view to sheep, for it is not so good for other stock many acres of it have been cultivated on his farm for sheep, and it has answered well when kept close fed. Marshall, in his *Midland Counties*, mentions it as a good grass for cows and other cattle, but bad for horses. In his *Rural Economy of Yorkshire*, he, however condemns it altogether.

5666. *According to Sinclair of Woburn*, "it appears to be generally disliked by all sorts of cattle. The produce is not so great as a view of it in the fields would indicate but being left almost entirely untouched by cattle, it appears the most productive part of the herbage. The hay which is made of it, from the number of downy hairs which cover the surface of the leaves, is soft and spongy and disliked by cattle in general. The Woburn experiments lead to the conclusion that the *Holcus mollis* is a better hay plant than the species here noticed but as that is a more durable perennial it is less fitted for the temporary purposes of this section.

5667 *The culture of these grasses* may be considered the same as that of rye-grass, which was discussed when treating of clover and rye-grass. (5540.) The seeds of all of them are sold by the principal seedsmen, or may be gathered on grass-fields, or hedge wastes, by women or children at an easy rate.

#### SUBJECT 2. Tall or Hay Grasses of permanent Duration.

5668. *No permanent grass* has been found equal to the rye-grass for the purposes of convertible husbandry, but others have been selected which are considered superior for hay meadows. The principal of these are the fescue, fox-tail, and meadow-grass. Agriculturists, indeed, are not all agreed on the comparative merits of these grasses with rye-grass; but there are none who do not consider it advisable to introduce a portion of each, or most of these species along with rye-grass, in laying down lands to permanent pasture. The nutritive products of these grasses, of perennial rye-grass, and of that singular grass *luzin*, are thus given by Sir H. Davy:—

Synonymic Name.	English Name.	In 100 Parts.				
		Whole quantity of soluble or nutritive matter.	Moisture or water.	Starch, dextrin or sugar.	Gluco- or albumen.	Extract or matter rendered soluble during re-portion.
<i>Festuca lolacea</i> (fg 790. c)	Spiked fescue grass	19	15	8	—	2
<i>Holcus odoratus</i>	Sweet-scented soft grass	32	73	4	—	6
<i>Anthoxanthum verum</i>	Sweet-scented vernal grass	50	43	4	—	3
<i>Alopecurus pratensis</i> (d)	Meadow fox tail grass	33	94	3	—	6
<i>Poa fertilis</i> (e)	Fertile meadow grass	78	65	6	—	7
<i>trivialis</i> (f)	Roughish meadow grass	39	99	5	—	6
<i>Cynodorus crinitus</i>	Crested dog-h-tail grass	35	98	3	—	4
<i>Lolium perenne</i>	Perennial rye grass	39	95	4	—	5
<i>varum</i>	varum	64	46	5	1	2
<i>Agrostis stolonifera</i>	Flourish cut in winter	76	64	8	1	3

5669. Of the fescue grass there are three species in the highest estimation as meadow hay grasses, viz. the meadow, tall, and spiked fescue (fg 790 a, b, c.)

5670. The *F. pratensis* (a), or the meadow or fertile fescue grass is found in most rich meadows and pastures in England, and is highly grateful to every description of stock. It is more in demand for laying down meadows than any other species except the rye grass. By the Woburn experiments, the value of this grass at the time the seed is ripe, is to that of the grass at the time of flowering, as 6 to 18. The loss which is sustained by leaving the crop of this grass till the seed be ripe is very great. That it loses more of its weight in drying at this stage of growth than at the time of flowering perfectly agrees with the deficiency of nutritive matter in the seed crop, in proportion to that in the flowering crop the straws being succulent in the former they constitute the greatest part of the weight but in the latter they are comparatively withered and dry consequently the leaves constitute the greatest part of the weight. It may be observed here that there is a great difference between straws or leaves that have been dried after they were cut in a succulent state, and those which are dried by nature while growing. The former retain all their nutritive powers but the latter if completely dry, very little if any.

5671. The tall or infertile fescue grass (*Festuca elatior* E. B. & S.) is closely allied to the *Festuca pratensis* from which it differs in little, except that it is larger in every respect. The produce is nearly three times that of the *F. pratensis*, and the nutritive powers of the grass are superior in direct proportion, as 6 to 8. The proportional value which the grass at the time the seed is ripe bears to the grass at the time of flowering is as 15 to 80. The proportional value which the grass of the lattermath bears to that of the crop, is as 16 to 50; and to the grass at the time the seed is ripe as 13 to 16 inverse. Curtis observes, that as the seeds of this plant, when cultivated, are not fertile, it can only be introduced by parting its roots and planting them out. In this there would, says he, be no great difficulty provided it were likely to answer the expense, which he is strongly of opinion it would in certain cases. Indeed he has often thought that meadows would be best formed by planting out the roots of grasses, and other plants, in a regular manner and that, however singular such a practice may appear at present, it will probably be adopted at some future period this great advantage would, he says, stand it, noxious weeds might be more easily kept down until the grasses and other plants had established themselves in the soil.

5672. The spiked fescue grass, or dandel fescue grass (*Festuca lolacea* L. c), resembles the rye-grass in appearance, and the tall fescue grass in the infertibility of its seeds. It is considered superior to rye grass either for hay or permanent pasture, and improves in proportion to its age which is the reverse of what takes place with the rye-grass.

5673. The meadow fox-tail grass (*Alopecurus pratensis*, d) is found in most meadows and when the soil is neither very moist nor very dry, but in good heart, it is very productive. It also does well on water meadows. Sheep and horses seem to have a greater relish than oxen for this grass.

5674. In the Woburn experiments It was tried both on a sandy loam and a clayey loam, and the result gave nearly three fourths of produce greater from a clayey loam than from a sandy soil, and the grass from the latter is comparatively less value, in proportion as 4 to 6. The straw produced by the sandy soil are deficient in number, and in every respect less than those from the clayey loam which will account for the unequal quantities of the nutritive matter afforded by them but the proportional value in which the grass of the lattermath exceeds that of the crop at the time of flowering, is as 4 to 5 a difference which appears extraordinary when the quantity of flower stalks which are in the grass at the time of flowering is considered. In the *Anthoxanthum odoratum* the proportional difference between the grass of these crops is still greater nearly as 4 to 9 in the *Poa pratensis* they are equal but in all the

after flowering grasses experimented upon, the flowering straws of which resemble those of the *Alopecurus pratensis*, or *Anthoxanthum odoratum*, the greater proportional value is always, on the contrary found in the grass of the flowering crop. Whatever the cause may be it is evident that the loss sustained by taking the crops of these grasses at the time of flowering is considerable. The proportional value which the grass at the time of flowering bears to that at the time the seed is ripe is as 5 to 8. The proportional value which the whole of the lattermath crop bears to that at the time the seed is ripe, is as 5 to 9 and to that at the time of flowering proportionally as 13 to 24. Next to the fescue this grass is in the greatest reputation for laying down mowing grounds but it is unfortunately subject to the rust in some seasons.

5675 Of the meadow grass there are two species in esteem as hay plants, the smooth-stalked, and roughish. These plants compose the greater part of the celebrated Orcheston meadows near Salisbury and also of the meadows near Edinburgh.

5676 The great or smooth stalked meadow grass, the spear grass of America (*Poa pratensis*, L.) is distinguished by its height, smooth stem, and creeping roots. According to Solé it is the best of all the grasses its foliage begins to shoot and put on a fine verdure early in the spring but not so soon as some other grasses. Every animal that eats grass is fond of it, while it makes the best hay and affords the richest pasture. It abounds in the best meadows about Lakenock and Chippenham, and has the valuable property of abiding in the same land, while most other grasses are continually changing. According to some it delights in rather a dry than a moist soil and situation, on which account it keeps its verdure better than most others in dry seasons but it thrives most luxuriantly in rich meadows.

5677 By the Woburn experiments the proportional value in which the grass of the lattermath exceeds that of the flowering crop, is as 6 to 7. The grass of the seed-crop, and that of the lattermath, are of equal value. The grass is therefore, of least value at the time the seed is ripe; a loss of more than one fourth of the value of the whole crop is sustained if it is not cut till that period the straws are then dry and the root-leaves in a sickly decaying state those of the lattermath, on the contrary are luxuriant and healthy. This species sends forth flower stalks but once in a season, and those being the most valuable part of the plant for the purpose of hay it will, from this circumstance, and the superior value of the grass of the lattermath, compared to that of the seed-crop, appear well adapted for permanent pasture. It was of this grass that the American prize bouquet, in imitation of Leghorn was manufactured by Miss Woodhouse.

5678 The roughish meadow grass (*Poa trivialis* L.) delights in moist, rich, and sheltered situations when it grows two feet high, and is very productive. By the Woburn experiments it appears that the proportional value in which the grass of the seed crop exceeds that at the time of flowering is as 8 to 11. The proportional value by which the grass of the lattermath exceeds that of the flowering crop, is as 8 to 12 and that of the seed crop, as 11 to 12. Here, then is a satisfactory proof of the superior value of the crop at the time the seed is ripe, and of the consequent loss sustained by taking it when in flower the produce of each crop being nearly equal. The deficiency of hay in the flowering crop in proportion to that of the seed crop, is very striking. Its superior produce, the highly nutritive powers which the grass seems to possess and the season in which it arrives at perfection, are merits which distinguish it as one of the most valuable of those grasses which affect moist rich soils and sheltered situations but on dry exposed situations, it is altogether inconsiderable it yearly diminishes, and ultimately dies off not unfrequently in the space of four or five years.

5679 The above are six of the best British grasses, for either dry or watered meadows. The seeds of the meadow fescue fox tail, and smooth and rough meadow grasses may be had from the seedsmen and they are sown in various proportions with the clovers and rye-grass. The seeds of the two sorts of meadow grass are apt to stick together and require to be well mixed with the others before being sown. The tall and spiked fescue grasses, having a number of barren flowers, are not prolific in seeds, and they are therefore seldom to be got at the seed-shops though they may occasionally be had there gathered from plants in a wild state.

5680 As hay grasses adapted for particular soils and situations, the cat's tail or Timothy flowering fescue, and fionn grass, have been recommended but it cannot be said that the opinions of cultivators are unanimous in their favour. Timothy has certainly been found to answer well on moist, peaty soils, and in several cases fionn also.

5681 The cat's tail or Timothy grass (*Phleum pratense* L., fig. 791 a) is a native plant,

and found both in dry and moist soils. It was first brought into notice by Timothy Hudson, about 1780, who introduced it from Carolina, where it was in great repute. On moist rich soils it is a prolific grass, but late on dry soils it is good for little, and for cultivation in any way is disapproved of by Withering, Swaine, Curtis, and others, as having no properties in which it is not greatly surpassed by the *Alopecurus pratensis*.

5682 The Woburn experiments however present this grass as one of the most prolific for hay. Sixty four drachms of the straws afforded seven drachms of nutritive matter. The nutritive power of the

straw simply, therefore, exceed those of the leaves, in the proportion of 38 to 8; the nutritive powers of the grass, at the time of flowering, exceed those of the grass at the time the seed is ripe, in the proportion of 10 to 23; and the nutritive powers of the latter than those of the grass of the flowering crop, in the proportion of 8 to 10. The comparative merits of this grass will, from the above particulars, appear to be very great, in which may be added the abundance of fine foliage that it produces early in the spring. In this respect it is inferior to *Poa fertilis* and *Poa angustifolia* only. The value of the straw at the time the seed is ripe, exceeds that of the grass at the time of flowering, in the proportion of 38 to 10, a circumstance which raises it above many others for from this property its valuable early foliage may be deposited to an advanced period of the season, without injury to the crop of hay, treatment which is grasses that send forth their flowering straws early in the season would cause a loss of nearly one half in the value of the crop, as clearly proved by former examples and this property of the straws makes the plant peculiarly desirable for hay. In moist and peaty soils it has in various instances been found highly productive.

5683. *The floating sward grass, Festuca fluitans* *b*) is found in rich swamps, especially in Cambridgeshire, where it is said to give the peculiar flavour to Cottenham and Cheddar cheese. It is also found in ditches and ponds in most parts of the country.

5684. *It is generally denominated by every description of stock not excepting hogs and ducks, and geese eagerly devour the seeds, which are small, but very sweet and nourishing. They are collected in several parts of Germany and Poland under the name of manna-seeds (achwede), and are esteemed a delicacy in soups and gruels. When ground to meal, they make bread very little inferior to that from wheat. The bran is given to horses that have the worms but they must be kept from water for some hours afterwards. Geese, and other water-fowl, are very fond of the seeds. So also are fish, trout in particular thrive in those rivers where this grass grows in plenty. It has been recommended to be sown on meadows that admit flooding but Curtis justly remarks, that the fete-fescue will not flourish except in land that is constantly under water or converted into a bog or swamp.*

5685 *The water meadow grass (Poa aquatica, c) is found chiefly in marshes, but will grow on strong clays, and yield, as the Woburn experiments prove, a prodigious produce flowering from June to September. It is one of the largest of our grasses.*

5686. *In the fens of Cambridgeshire Lincolnshire &c. immense tracts, that used to be overflowed and to produce useless aquatic plants, and which though drained by xills, still retain much moisture, are covered with this grass, which not only affords rich pasturage in summer but forms the chief part of the winter fodder. It has a powerfully creeping root, and bears frequent mowing well. It is sometimes cut thrice in one season near the Thames. It grows not only in very moist ground, but in the water itself; and with cat-tail, burr reed, &c. soon fills up ditches, and occasions them to require frequent cleaning. In this respect it is a formidable plant, even in slow rivers. In the Isle of Ely they cleanse them by an instrument called a bear which is an iron roller with a number of pieces of iron, like small spades, fixed to it: this is drawn up and down the river by horses walking along the bank, and tears up the plants by the roots, which float, and are carried down the stream. The grass was, however cultivated at Woburn on a strong tenacious clay and yielded considerable produce.*

5687 *The sorin grass (Agrostis stolonifera, d) is a very common grass both in wet and dry rich and poor situations. Few plants appear to be more under the influence of local circumstances than this grass. On dry soils it is worth nothing but on rich marl soils, and in a moist soil, if we may put confidence in the accounts given of its produce in Ireland, it is the most valuable of all herbage plants.*

5688. *It was first brought into notice by Dr Richardson in 1809, and subsequently extolled, and its culture detailed in various pamphlets by the same gentleman. It appears to be exclusively adapted for moist peat soils or bogs. In The Code of Agriculture it is said, "On mere bogs, the sorin yields a great weight of herbage, and is, perhaps, the most useful plant that bogs can produce." According to Sir H. Davy the sorin grass, to be in perfection, requires a moist climate or a wet soil; and it grows luxuriantly in cold clays unfitted for other grasses. In light sands, and in dry situations, its produce is much inferior as to quantity and quality. He saw four square yards of sorin grass cut in the end of January in a meadow exclusively appropriated to the cultivation of sorin by the Countess of Hardwicke, the soil of which is a damp stiff clay. They afforded twenty-eight pounds of fodder of which one thousand parts afforded sixty four parts of nutritive matter consisting nearly of one sixth of sugar and five sixths of mucilage with a little extractive matter. In another experiment, four square yards gave twenty seven pounds of grass. Lady Hardwicke has given an account of a trial of this grass; wherein twenty three milch cows, and one young horse, besides a number of pigs, were kept a fortnight on the produce of one acre. On the Duke of Bedford's farm, at Maulden, sorin hay was placed in the racks before horses, in small distinct quantities alternately with common hay; but no decided preference for either was manifested by the horses in this trial. Sorin has been tried in the highlands of Scotland, and a premium awarded in 1821 for a field of three acres planted on land previously worth very little, at Apple in Argyleshire. (Highl. Soc. Trans vol. vi. p. 528.) Hay-ma has also been made from sorin, and found useful in rearing calves, being mixed with oatmeal and skimmed milk. (Ibid. p. 533.)*

5689. *There are other species of Agrostis as the A. palustris and ripens, and some varieties of the A. stolonifera, that on common soils are little different in their appearance and properties from sorin. On one of these, the narrow-leaved creeping-bent (A. stolonifera var angustifolia) the following remarks are made in the account of the Woburn experiments. "From a careful examination of the creeping-bent with narrow leaves, it will doubtless appear to possess merits well worthy of attention, though perhaps not so great as they have been supposed, if the natural place of its growth and habits be impartially taken into the account. From the couchant nature of this grass, it is denominated couch-grass, by practical men; and from the length of time that it retains the vital power after being taken out of the soil it is called aquile, quick, full of life, &c."*

5690. *The culture of sorin is different from that of other grasses. Though the plant will ripen its seeds on a dry soil, and these seeds being very small, a few pounds would be sufficient for an acre, yet it is generally propagated by stones or root-shoots. The ground being well pulverised, freed from weeds, and laid into such beds or ridges as the cultivator may think advisable; small drills an inch or two deep, and six or nine inches asunder, are to be drawn along its surface, with a hand or horse-hoe, or on soft lands with the hoe-rake. In the bottom of these drills the sorin shoots (whether long or short is of no consequence) are laid lengthways, so that their ends may touch each other and then lightly covered with a rake, and the surface rolled to render it fit for the sythe. In six months the whole surface will be covered with verdure, and if the planting be performed early in spring, a large crop may be had in the following autumn. Any season will answer for planting but one likely to be followed by showers and heat is to be preferred. Those who wish to cultivate this grass will consult Dr. Richardson's New Essay on Florin Grass (1815) and also The Farmer's Magazine for 1810 14. Our opinion is, that neither sorin, Timothy nor fescue, is ever likely to be cultivated in Britain; though the latter two may perhaps succeed well on the bogs and moist rich soils of Ireland, where, to second the influence of the soil, there is a moist warm climate.*

5691. A number of other species of tall grasses, well adapted for meadows and hay making, might be enumerated but we have deemed it better to treat only of the most popular sorts, of which seeds may be purchased all the others of any consequence will be found in a tabular view (Sect. III), accompanied by a summary statement of their products in hay and aftermath nutritive matter, and general character.

5692. The preparation of the soil, and the sowing of the usual meadow grasses, differ in nothing from those of clover and rye-grass already given. The after-treatment of dry meadows, including the making of natural hay will be found in the succeeding Chapter on the management of grass-lands that of watered meadows was naturally given when treating of their formation. (4431)

## SECT. II. Grasses chiefly adapted for Pasturage

5693. In treating of pasturage grasses we shall make a selection of such as have been tried to some extent, and of which the seeds are in the course of commerce. On soils in good condition, and naturally well constituted, no better grasses can be sown for pasturage than those we have described as tall grasses for hay-meadows but for early and late pasturage, and secondary soils, there are others much more suitable.

5694. The pasture grasses for early pasturage on all soils are the *Anthoxanthum odoratum* *Holcus odoratus*, *Avena pubescens*, and *Poa annua*.

5695. The pasture grasses for late herbage on all soils are chiefly the different species of *Agrostis* and *Phleum*.

5696. The pasture grasses for poor or secondary soils are the *Cynodorus cristatus*, *Festuca duriacula* and *ovina*, *Poa compressa*, *crispata*, and *angustifolia*.

5697. The grasses that afford most nutritive matter in early spring are the fox tail grass and the vernal grass the former has been already mentioned as one of the best hay grasses.

5698. The sweet-scented vernal grass (*Anthoxanthum odoratum*, fig. 792. a) is common in almost all

pastures, and is that which gives the fragrance to natural or meadow hay. It is chiefly valuable as an early grass for though it is eaten by stock, it does not appear to be much relished by them. From the Woburn experiments, it appears that the smallness of the produce of this grass renders it improper for the purpose of hay but its early growth and the superior quantity of nutritive matter which the aftermath affords, compared with the quantity afforded by the grass at the time of flowering cause it to rank high as a pasture-grass, on such soils as are well fitted for its growth such as peat-bogs, and lands that are deep and moist.

5699. The showy oat grass (*Avena pubescens* b) according to the Woburn experiments, possesses several good qualities, which recommend it to particular notice. It is hardy early and more productive than many others which affect similar soils and situations. Its growth after being cropped is tolerably rapid although it does not attain to a great length if left growing; like the *Poa pratensis* it sends forth flower stalks but once in a season, and it appears well calculated for permanent pasture on rich light soils.

5700. The annual meadow grass (*Poa annua*, c) is the most common of all grasses, and the least absolute in its habits. It is almost the only grass that will grow in towns and near works where the smoke of coal abounds. Though an annual grass, it is found in most meadows and pastures perpetually flowering, and affording an early sweet herbage, relished by all stock, and of as great importance to birds as what is to man. It hardly requires to be sown, as it springs up every where or itself. However it may not be amiss to sow a few pounds of it per acre wherever perpetual pasture (not hay) is the object.

5701. The fine leaf grass (*Agrostis vulgaris*, d) is one of the most common grasses, and, according to the Woburn experiments, one of the earliest. The *A. patrisis* is nearly as early in producing its foliage, though both flower late, and neither is very prolific either in bulk or nutritive matter.

5702. The narrow-leaved meadow grass (*Poa angustifolia*, e) though it flowers late yet is remarkable for the early growth of the leaves. According to the Woburn experiments the leaves attain to the length of more than twelve inches before the middle of April, and are soft and succulent. In May however when the flower-stalks make their appearance, it is subject to the disease termed rust, which affects the whole plant, the consequence of which is manifest in the great deficiency of produce in the crop at the time the seed is ripe, being then one half less than at the time of the flowering of the grass. Though this disease begins in the straw, the leaves suffer most from its effects, being at the time the seed is ripe completely dried up. The straw, therefore, constitutes the principal part of the crop for mowing, and they contain more nutritive matter in proportion than the leaves. This grass is evidently most valuable for permanent pasture, for which in consequence of its superior, rapid, and early growth, and the disease beginning at the straw, nature seems to have designed it. The grasses which approach nearest to this in respect of early produce of leaves, are the *Poa fertilis* *Dioclyis glomerata*, *Phleum pratense*, *Alopecurus pratensis*, *Avena elatior* and *Bromus villosus* all grasses of a coarser kind.

5703. The best natural pastures of England, examined carefully during various periods of the season, were found by Sinclair of Woburn to consist of the following plants:—

<i>Deschampsia flexuosa.</i>	<i>Phleum pratense.</i>	<i>Poa trivialis.</i>	<i>Poa annua.</i>
<i>Briza media.</i>	<i>Anthriscus silvestris.</i>	<i>Lolium perenne.</i>	<i>Avena pratensis.</i>
<i>Festuca ovina.</i>	<i>Stellaria media.</i>	<i>Trifolium arvense (frequent).</i>	

These afford the principal grass in the spring, and also a great part of the summer produce:—

<i>Alnus arvensis.</i>	<i>Phleum pratense.</i>	<i>Stellaria media.</i>	<i>Lolium perenne.</i>
<i>Stellaria media.</i>	<i>Poa trivialis.</i>	<i>Trifolium pratense.</i>	
<i>Cynodon dactylon.</i>	<i>Poa annua.</i>	<i>Trifolium repens.</i>	

These yield produce principally in summer and autumn:—

<i>Achillea millefolium.</i>	<i>Agrostis stolonifera and pilulifera.</i>	<i>Trifolium repens.</i>
------------------------------	---	--------------------------

These vegetate with most vigour in autumn:—

<i>Ruminantia herb.</i>	<i>Plantago lanceolata.</i>	<i>Rumex acetosa.</i>
-------------------------	-----------------------------	-----------------------

The first and last of these plants are to be considered injurious; and the other is of little value as herbage. (*Hort. Gram. Wob. 2d edit. 133.*)

5704. The above mixture sown at the rate of four or five bushels to the acre, on well prepared soil with-out corn or other crop of any kind would hardly fail of producing excellent pasture in the following year and for an indefinite period. The best time for sowing is July or August, as spring-sown seeds are apt to suffer with the droughts of June and July. Fifteen of the above sorts are to be had from the seed-shops and all of them may be gathered from natural pastures, or bespoke from collectors. Sinclair of Woburn, having entered into the seed and nursery business and having expressed his intention to devote his particular attention to supplying the public with grass and other agricultural seeds, will probably render such seeds more common in commerce. (*Ibid. by Cormack Son, and Sinclair.*)

5705. Of late pasture grasses the different species of cat-tail (*Phleum*) and bent-grass (*Agrostis*) are the chief and especially the Timothy and foin grass. The grasses, Sir H. Davy observes, that propagate themselves by stolons, the different species of *Agrostis*, supply pasture throughout the year and the concrete sap, stored up in their joints, renders them a good food even in winter.

5706. Of pasture grasses for inferior soils one of the most durable is the dog's-tail grass (*Cynosurus cristatus*, fig. 793 a). This is a very common grass on dry clayey, or firm

surfaces. It is one of the best grasses for parks, being highly relished by the South Down sheep and deer.

5707. The hard fescue grass (*Festuca duriuscula*, b) is one of the best of the dwarf sorts of grasses. It is grateful to all kinds of cattle. In some very kind of it at Woburn they crop it close to the roots, and neglect the *Festuca ovina* and *Festuca rubra*, which grow contiguous to it. It is present in most good meadows and pastures, and, with *F. ovina*, is the best for lawns.

5708. The *Festuca glabra* (c) and *hordelymus* (d) greatly resemble the hard fescue, and may be considered equally desirable as pasture and lawn grasses.

5709. The golden oat grass (*Alnus flavescens*) is very generally cultivated, and appears, from the Woburn experiments, to be a very valuable grass for pasture on a clayey soil.

5710. Of pasture grasses for inferior soils and upland situations, one of the principal is the *Festuca ovina*, or sheep's fescue grass (fig. 794 a). This

grass is peculiarly adapted for hilly sheep or stables. It is a low dwarf grass, but relished by all kinds of cattle. According to Sinclair's experience, on dry soils that are incapable of producing the larger sorts, this should form the principal crop, or rather the whole for it is seldom or never in its natural state, found intimately mixed with others, but by itself.

5711. The *Poa alpina* (b) *Alnus alpina* and *Alnus arvensis* (c), *Briza media* (d), and *Agrostis stolonifera* and *ovifolia*, are all dwarf mountain grasses, well adapted for hilly parks or lawns.

5712 *On the culture of those grasses it is unnecessary to enlarge as it must obviously be the same as that of rye-grass or any of the others.*

5713. *The chief difficulty is to get the seed in sufficient quantity for which a good mode is to contract with a seedsmen, a year beforehand for the quantity wanted. With all the pasture grasses, except the last ones, we should recommend at least half the seed to be that of the perennial rye-grass and we think it should also form a considerable part of the seeds used in laying down all meadows, except those for the aquatic or solumiferous grasses. These, if they thrive are sure to choke and destroy it, and therefore neither rye-grass, nor any other grass, should ever be sown with Timothy grass or fescue.*

5714 *The formation of grassy surfaces by distributing pieces of turf over them has long been practised in gardening, in levelling down raised, or filling up hollow, fences, and in other cases of partially altering a grassy surface.*

5715 *It is said to have been first used in agriculture by Whitworth, of Acra-house, Lancashire and in 1818 it was brought forward on a large scale by John Blomfield, of Warham, in Norfolk, a tenant of Coke's. Blomfield planted eleven acres in this way. An account of the process, which is styled transplanting turf, or inoculating land with grass, has been published by Francis Blake, Coke's steward (*On the Conversion of Arable Land into Pasture* 12mo, 1817).*

5716. *An abstract of the process of transplanting turf and an opinion on it, are thus given in The Code of Agriculture. A piece of good clean, sweet old turf which ought principally to consist of fibrous-rooted plants is cut into small pieces of about three inches square, and placed about six inches apart on the surface of ground prepared for that purpose. In this way one acre of turf will plant nine acres of arable land. The pieces of turf should be evenly placed with the grass side uppermost, and the plants pressed well into the ground. No more turf should be cut, earned, and spread in any one day than is likely to be planted before night. If the transplanted turf is found deficient in any particular species of favourite plants, as white clover permanent red clover &c. the seeds of those plants should be sown upon the young pasture in April. When the ground is in proper temper (between wet and dry) the pasture should be frequently well pressed down by heavy rollers, which will cause the plants to extend themselves along the ground rather than rise into tufts, which otherwise they would be apt to do. No stock should be permitted to feed upon the transplanted pasture in the first spring or summer nor until the grasses have perfected and shed their seeds. Indeed the pasturing should be very moderate until the mother grass-plants and their young progeny have united and formed a compact turf. The expense of this operation is about 2/ 10s per statute acre without making any allowance for the charges incurred by summer following the arable land on which the turf has been transplanted. nor for the year's rent, poor's rates, and taxes for that year. Not for restoring the land whence the turf plants were taken to its previous state. This plan seems to be well calculated to promote the improvement of light soils not naturally of a grassy nature for the grasses and their roots being once formed on a rich soil will probably thrive after wards even on a poor one, as they will derive a considerable proportion of their nourishment from the atmosphere. For light and gravelly soils, therefore, where permanent pasture is desirable, the plan cannot be too strongly recommended, and if it were found to answer on peat, for the surface was pared for the recovery of the plants, and burnt to promote their growth, it would be a most valuable acquisition to sheep farmers in many districts of the country. Thus far Sir John Sinclair but, from facts related by Sinclair of Woburn it appears to be a plan of little or no merit, and only brought into notice by its novelty (*H G Wob 2d edit 420, 421*).*

### SECT III General View of the Produce Uses, Character and Value of the principal British Grasses according to the Result of John Duke of Bedford's Experiments at Woburn.

\*5717 *In all permanent pastures Sir H. Davy observes, nature has provided a mixture of various grasses, the products of which differs at different seasons. Where pastures are to be made artificially such a mixture ought to be imitated and, perhaps, pastures superior to the natural ones may be formed by selecting due proportions of those species of grasses fitted for the soil, which afford respectively the greatest quantities of spring, summer, lattermath, and winter produce. a reference to the results of the Woburn experiments, he adds will show that such a plan of cultivation is very practicable.*

5718 *The manner in which these experiments were conducted is thus described — "Spots of ground each containing four square feet, in the garden at Woburn Abbey were enclosed by boards in such a manner that there was no lateral communication between the earth included by the boards, and that of the garden. The soil was removed in these enclosures, and new soils supplied or mixtures of soils were made in them to furnish as far as possible to the different grasses those soils which seem most favourable to their growth a few varieties being adopted for the purpose of ascertaining the effect of different soils on the same plant. The grasses were either planted or sown and their produce cut and collected, and dried at the proper seasons, in summer and autumn by Sinclair Esq. Grace's gardener. For the purpose of determining, as far as possible, the nutritive powers of the different species, equal weights of the dry grasses or vegetable substances were acted upon by hot water till all their soluble parts were dissolved, the solution was then evaporated to dryness by a gentle heat in a proper stove, and the matter obtained carefully weighed. This part of the process was likewise conducted with much address and intelligence by Sinclair by whom all the following details and calculations are furnished. The dry extracts supposed to contain the nutritive matter of the grasses, were sent to me for chemical examination. The composition of some of them is stated minutely but it will be found from the general conclusions, that the mode of determining the nutritive power of the grasses, by the quantity of matter they contain soluble in water is sufficiently accurate for all the purposes of agricultural investigation (*Ag. Chem. app*).*

5719. *The leading results of these experiments we have endeavoured to present in a tabular view further details will be found in the paragraphs (antecedent and posterior) referred to in the first column. On the other columns of the table, it may be observed, that the height is given more by a guess than measurement, and after the appearance of the plants in a state of nature or medium soil. It is to be regretted that the height of the plants was not included in the published details. The time of flowering is given as it took place at Woburn on which it is observed, that to decide positively the exact period or season when a grass always comes into flower and perfects its seed, will be found impracticable for a variety of circumstances interfere. Each species seems to possess a peculiar life in which various periods may be distinctly marked, according to the varieties of its age, of the seasons, soils, exposures, and modes of culture.*

5720. *The soils, as denominated in the column devoted to them, are thus described 1st, By loam, is meant any of the earths combined with decayed animal or vegetable matter. 2d, Clayey loam, when the greatest proportion is clay. 3d, Sandy loam, when the greatest proportion is sand. 4th, Brown loam, when the greatest proportion consists of decayed vegetable matter. 5th, Rich black loam, when sand, clay, animal, and vegetable matters are combined in unequal proportions, the clay greatly divided, being in the least proportion, and the sand and vegetable matter in the greatest. The terms light sandy soil, light brown loam, &c. are varieties of the above, as expressed. The abbreviations of the names of books and native soils, with all abbreviations used in this work, will be found explained in the General Index.*

5721

5792. On the nutritive products, Sir H. Davy has the following valuable remarks, some of which, concerning the mode in which the animal economy is operated on by the different substances composing the nutritive matter the agriculturist will find useful, as applied to the tables before given (5000, 5190, &c.) of the nutritive products of the corn, legumes, and roots. The only substances which Sir H. Davy detected in the soluble matters procured from the grasses, are mucilage, sugar, bitter extract, a substance analogous to albumen and different saline matters. Some of the products from the aftermath crops gave feeble indications of the tanning principle. In the experiments made on the quantity of nutritive matter in the grasses, cut at the time the seed was ripe, the seeds were always separated, and the calculations of nutritive matter made from grass and not hay.

5793. The order in which these substances are nutritive is thus given:—"The albumen, sugar, and mucilage, probably when cattle feed on grass or hay are for the most part retained in the body of the animal, and the bitter principle, extract, saline matter and tannin, when any exist, probably for the most part are voided in the excrement, with the woody fibre. The extractive matter obtained by boiling the fresh dung of cows, is extremely similar in chemical characters to that existing in the soluble products from the grasses. And some extract, obtained by blanching the dung of sheep and of deer, which had been feeding upon the *L. hum. perenne*, *Dactylis glomerata*, and *Trifolium repens*, had qualities so analogous to those of the extractive matters obtained from the leaves of the grasses, that they might be mistaken for each other. The extract of the dung, after being kept for some weeks, had still the odour of hay. Suspecting that some undigested grass might have remained in the dung which might have furnished mucilage and sugar as well as bitter extract, I examined the soluble matter very carefully for these substances. It did not yield an atom of sugar, and scarcely a perceptible quantity of mucilage." Singular in comparing the qualities of the soluble matter of the matted leaves of the *L. hum. perenne*, *Dactylis glomerata*, and *Trifolium repens*, and that obtained from the dung of cattle fed upon them, found their relative proportions as 50 to 13.

5794. From these facts it appears probable that the bitter extract, though soluble in a large quantity of water is very little nutritive, but probably it serves the purpose of preventing to a certain extent, the fermentation of the other vegetable matters, or in modifying or assisting the function of digestion, and may thus be of considerable use in forming a constituent part of the food of animals. A small quantity of bitter extract and saline matter is probably all that is needed, and beyond this quantity the soluble matters must be more nutritive in proportion as they contain more albumen, sugar, and mucilage, and less nutritive in proportion as they contain other substances.

5795. In comparing the composition of the soluble products afforded by different crops from the same grass, Sir H. Davy found, in all the trials, the largest quantity of truly nutritive matter in the crop cut when the seed was ripe, and least bitter extract and saline matter. Most extract and saline matter in the autumnal crop, and most saccharine matter in proportion to the other ingredients, in the crop cut at the time of flowering.

5796. The greater proportion of leaves in the spring, and particularly in the late autumnal crop, accounts for the difference in the quantity of extract, and the inferiority of the comparative quantity of sugar in the summer crop, probably depends upon the agency of light, which tends always in plants to convert saccharine matter into mucilage or starch. Amongst the soluble matters afforded by the different grasses, that of the *Phytolacca arborescens* (Ag. 711 c) was remarkable for the quantity of saccharine matter it contained, amounting to more than one third of its weight. The soluble matters from the different species of *Festuca*, in general, afforded more bitter extractive matter, than those from the different species of *Poa*. The nutritive matter from the seed crop of the *Poa compressa* was almost pure mucilage. The soluble matter of the seed crop of *Phytolacca arborescens*, or *mandarin* cat-tail, afforded more sugar than any of the *Poa* or *Festuca* species. The soluble parts of the seed crop of the *Holcus mollis*, and *Holcus lanatus*, contained no bitter extract, and consisted entirely of mucilage and sugar. Those of the *Holcus nodosus* afforded bitter extract, and a peculiar substance having an acrid taste, more soluble in alcohol than in water. All the soluble extracts of those grasses, that are most liked by cattle have either a saline or saccharine taste, that of the *Holcus lanatus* is similar in taste to gum arabic. Probably the *Holcus lanatus*, which is so common a grass in meadows, might be made palatable to cattle by being sprinkled over with salt.

5797. No difference was found in the nutritive products of the crops of the different grasses cut at the same season, which would render it possible to establish a scale of their nutritive powers, but probably the soluble matters of the aftermath crop are always from one sixth to one third less nutritive than those from the flower or seed crop. In the aftermath the extractive and saline matters are certainly usually in excess, but the aftermath hay mixed with summer hay, particularly that in which the fox tail and soft grasses are abundant, would produce an excellent food.

5798. *Anthriscus odoratus* L. B. — The proportional value which the grass, at the time of flowering, bears to that at the time the seed is ripe, is as 4 to 13. The proportional value which the grass of the aftermath bears to that at the time the seed is ripe, is nearly as 9 to 13.

5799. *Holcus arvensis* Host, G. A. — The proportional value which the grass, at the time of flowering, bears to that at the time the seed is ripe, is as 17 to 31. The grass of the aftermath crop, and that of the crop at the time of flowering, taking the whole quantity and their relative proportions of nutritive matter, are in value nearly as 6 to 10. The value of the grass, at the time the seed is ripe, exceeds that of the aftermath in proportion as 31 to 17. Though this is one of the earliest of the flowering grasses, it is tender, and the produce in the spring is inconsiderable. If however the quantity of nutritive matter which it affords be compared with that of any of those species which flower nearly at the same time, it will be found greatly superior. It sends forth but a small number of flower stalks, which are of a slender structure compared to the size of the leaves. This will account, in a great measure, for the equal quantities of nutritive matter afforded by the grass at the time of flowering, and the aftermath.

5799. *Cynodon caryoides* E. B. (*Setaria caryoides* E. of P. 1070). — The produce of this grass is greater than the *anthriscus* would demand, the leaves seldom attain to more than four or five inches in length, and the flower-stalks seldom arise to more. Its growth is not rapid after being cropped, nor does it seem to withstand the effects of frost, which if it happens to be severe and early in the spring checks it so much as to prevent it from flowering for that season, otherwise, the quantity of nutritive matter which the grass affords (for the stems are very inconsiderable) would rank it as a valuable grass for permanent pastures.

5799. *Setaria pedunculata* E. B. (*Trifolium pedunculata* E. of P. 1082). — The proportional value which the grass at the time of flowering bears to that at the time the seed is ripe, is as 6 to 8. The proportional value which the grass at the time of flowering bears to that of the aftermath is as 6 to 3. The grass of the seed-crop, and that of the aftermath, are of equal value. The downy hairs which cover the surface of the leaves of this grass, when growing on poor light soils, almost entirely disappear when it is cultivated on a richer soil.

5799. *The arvensis var. pedunculata* E. B. — If the produce of this variety be compared with that of

*Poa pratensis*, it will be found less; nor does it seem to possess any superior excellence. The superior nutritive power does not make up for the deficiency of produce by 50 lbs. of nutritive matter per acre.

5735. *Festuca hordeiformis* H. Cant. — This is rather an early grass, though later than any of the preceding species; its foliage is very fine, resembling the *F. duranensis*, to which it seems nearly allied, differing only in the length of the awns, and the glaucous colour of the whole plant. The considerable produce it affords, and the nutritive powers it appears to possess joined to its early growth, are qualities which strongly recommend it to further trial.

5736. *Festuca glauca* Curtis. — The proportional value by which the grass at the time of flowering exceeds that at the time the seed is ripe is as 6 to 12. The proportional difference in the value of the flowering and seed crops of this grass is directly the reverse of that of the preceding species, and affords another strong proof of the value of the straw in grass which is intended for hay. The straws at the time of flowering are of a very succulent nature, but, from that period till the seed be perfected, they gradually become dry and wiry. Nor do the root-leaves sensibly increase in number or in size, but a total suspension of increase appears in every part of the plant, the roots and seed-vessels excepted. The straws of the *Poa trivialis* are, on the contrary, at the time of flowering weak and tender, but as they advance towards the period of ripening they become firm and succulent after that period, however they rapidly dry up, and appear little better than a mere dead substance.

5737. *Festuca ovina* With. B. — The proportional value which the grass at the time the seed is ripe bears to that of the crop at the time of flowering is as 5 to 8. The proportional value which the grass of the lattermath bears to that of the crop at the time of flowering, is as 2 to 5, and to that of the crop, at the time the seed is ripe, is as 9 to 5. The general appearance of this grass is very similar to that of the *Festuca duranensis*. It is, however, specifically different, and inferior in many respects, which will be manifest on comparing their several produce with each other; but if it be compared with some other, now under general cultivation, the result is much in its favour the soil which it affects being only attended to.

5738. *Festuca rubra* With. B. — The proportional value which the grass at the time of flowering bears to that at the time the seed is ripe is as 5 to 8. This species is smaller in every respect than the preceding. The leaves are seldom more than from three to four inches in length. It affects a soil similar to that favourable to the growth of the *Festuca ovina*, for which it would be a probable substitute, as it will clearly appear on a comparison of their produce with each other. The proportional value which the grass of the lattermath bears to that at the time the seed is ripe is as 5 to 8, and is of equal value with the grass at the time of flowering.

5739. *Festuca ovina* E. B. — The dry weight of this species was not ascertained, because the smallness of the produce renders it entirely unfit for hay.

5740. *Festuca ciliolata* Thell. — This species is nearly allied to the *Festuca ovina* from which it differs little, except that it is larger in every respect. The produce, and the nutritive matter which it affords, will be found superior to those given by the *F. ovina*, if they are brought into comparison.

5741. *Briza media* Curt. Lond. (B. *medialis* E. of P. 1140.) — This species, like the *Festuca ciliolata*, is strictly annual; the above is therefore the produce for one year, which if compared with that of the least productive of the perennial grasses, will be found inferior and it must consequently be regarded as unworthy of culture.

5742. *Poa angustifolia* With. B. — In the early growth of the leaves of this species of *Poa*, there is a striking proof that early flowering in grasses is not always connected with the most abundant early produce of leaves. In this respect, all the species which have already come under examination are greatly inferior to that now spoken of. The culms are most valuable for the manufacture of the finest straw plait.

5743. *Avena sativa* Curt. (Hibiscus *semdensis* E. of P. 14627.) — This grass seeds forth flower straw during the whole season and the lattermath contains nearly an equal number with the flowering crop. It is subject to the rust, but the disease does not make its appearance till after the period of flowering, it affects the whole plant, and at the time the seed is ripe the leaves and straws are withered and dry. This accounts for the superior value of the lattermath over the seed crop, and points out the propriety of taking the crop when the grass is in flower.

5744. *Poa elatior* Curt. — The botanical characters of this grass are almost the same as those of the *Avena elatior* differing in the want of the awns only. It has the essential character of the *Holcus* (*Setaria*, male and hermaphrodite, calyx husks two-valved, with two *Setaria*); and since the *Avena elatior* is now referred to that genus, this may with certainty be considered a variety of it.

5745. *Festuca ovina* E. B. — The proportional value which the grass at the time the seed is ripe bears to that at the time of flowering, is as 5 to 14 nearly. The proportional value which the grass of the lattermath bears to that at the time of flowering, is as 5 to 14, and to that at the time the seed is ripe as 5 to 6. The above particulars will confirm the favourable opinion which was given of this grass when speaking of the *F. acrocladus*, and *F. glabra*. (5733. and 5735.) Its produce in the spring is not very great, but of the finest quality and at the time of flowering is considerable. If it be compared with those affecting similar soils, such as *Poa pratensis*, *Festuca ovina*, &c. either considered as a grass for hay or permanent pasture, it will be found of greater value.

5746. *Milium effusum*. — This species in its natural state seems confined to woods as its place of growth but the trial that is here mentioned confirms the opinion that it will grow and thrive in open exposed situations. It is remarkable for the lightness of the produce in proportion to its bulk. It produces foliage early in the spring in considerable abundance; but its nutritive powers appear comparatively little.

5747. *Poa maritima* E. B. — The proportional value which the grass of the lattermath bears to that at the time of flowering is as 4 to 18.

5748. *Avena pratincola* E. B. — The proportional value which the crop, at the time the seed is ripe, bears to that at the time of flowering, is as 4 to 9.

5749. *Briza media* Curt. — This species is annual and no valuable properties have as yet been discovered in the seed. It is only noticed on account of its being frequently found in poor grass lands, and sometimes in meadows. It appears, from the above particulars, to possess nutritive powers equal to some of the best perennial kinds if taken when in flower, but if left till the seed is ripe (which from its early growth is frequently the case) the crop is comparatively of no value, the leaves and straws being then completely dry.

5750. *Festuca latifolia* Curt. Lond. — The proportional value which the grass, at the time of flowering bears to that at the time the seed is ripe, is as 12 to 13, and the value of the lattermath stands in proportion to that of the crop, at the time of flowering, as 3 to 12, and to that of the crop taken at the time the seed is ripe, as 5 to 12. This species of *Festuca* greatly resembles the rye-grass, in habit and place of growth; it has excellences which make it greatly superior to that grass, for the purposes of either hay or permanent pasture. This species seems to improve in produce in proportion to its age, which is directly the reverse of the *Lolium perenne*.

5751. *Poa cristata* Curt. G. A. — The produce of this species, and the nutritive matter that it affords, are equal to those of the *Festuca ovina*, at the time the seed is ripe, they equally delight in dry soils. The greater bulk of grass, in proportion to the weight, with the comparative coarseness of the foliage, renders the *Poa cristata* inferior to the *Festuca ovina*.

5752. *Festuca ovina* E. B. (*Megasturus nemoralis* E. of P. 1118.) — This species is strictly annual; it is likewise subject to the rust; and, the produce being but little, it ranks as a very inferior grass.

5753. *Festuca ciliolata* E. B. — The proportional value which the grass, at the time the seed is ripe, bears to that at the time of flowering, is as 12 to 18. This grass, as has already been remarked, produces

a fine early foliage in the spring. The produce is very great, and its nutritive powers are considerable. It appears, from the above particulars, to be best adapted for hay. A very singular disease attacks, and sometimes nearly destroys, the seed of this grass the cause of this disease seems to be unknown; it is denominated *blow* by some. It appears by the seed swelling to three times its usual size, in length and thickness, and the want of the cord. Dr. Willdenow describes two distinct species of it. First, the simple *blow*, which is mealy and of a dark colour, without any smell or taste; secondly, the malignant *blow*, which is violet blue, or blackish, and internally too has a bluish colour, with a foetid smell, and a sharp pungent taste. Bread made from grain affected with this last species, is of a bluish colour and when eaten, produces cramps and sickness.

5752. *Reberus latifolius* Host G. A. — The proportional value which the grass, at the time of flowering, bears to that at the time the seed is ripe is as 6 to 14. This species greatly resembles the preceding, in habit and manner of growth, but is inferior to it in value, which is evident from the deficiency of its produce, and of the nutritive matter afforded by it. The whole plant is likewise coarser and of greater bulk in proportion to its weight. The seed is affected with the same disease which destroys that of the former species.

5753. *Poa trivialis* Curt. Lond. (*Glyceria hibernica* E. of P. 1000) — The above produce was taken from grass that had occupied the ground for four years during which time it had increased every year. It appears, therefore, contrary to what some have supposed, to be capable of being cultivated in perennial pastures.

5754. *Poa trivialis* Host, G. A. — If the nutritive powers and produce of this species be compared with any other of the same family, or such as resemble it in habit and the soil on which it affects, the superior will be found, which ranks this as one of the most valuable grasses. Next to the *Poa angustifolia*, it produces the greatest abundance of early foliage of the best quality which fully compensates for the comparative lateness of flowering.

5755. *Aristida colorata* Hort. Kew. — The strong nutritive powers which this grass possesses recommend it to the notice of occupiers of strong clayey lands which cannot be drained. Its produce is great, and the foliage will not be deteriorated course, if compared with grasses which afford a produce equal in quantity.

5756. *Hieracium pratense* E. B. — The specific characters of this species are much the same as those of the *Poa trivialis*, differing in the compressed figure of the straw and creeping root only. If the produce were of magnitude, it would be one of the most valuable grasses for it produces foliage early in the spring and possesses strong nutritive powers.

5757. *Avena fasciculata* Curt. Lond. (*Triadenum fasciculatum* E. of P. 1000) — The proportional value which the grass, at the time the seed is ripe, bears to that at the time of flowering, is as 9 to 15. The proportional value which the grass of the latter month bears to that at the time of flowering is as 5 to 15 and to that at the time the seed is ripe, as 5 to 9.

5758. *Reberus strictus* E. B. — 64 dr of the flowers afford of nutritive matter 22 dr. The nutritive powers of the straw and leaves are, therefore, more than twice as great as those of the flowers. This species, being strictly annual, is of comparatively little value. The above particulars show that it has very considerable nutritive powers, more than its name would imply if taken at the time of flowering but if left till the seed be ripe, it is, like all other annuals, comparatively of no value.

5759. *Hieracium molle* — 64 dr of the roots afford of nutritive matter 52 dr. The proportional value which the grass, at the time the seed is ripe, bears to that at the time of flowering, is as 14 to 18. The above details prove this grass to have merits, which if compared with those of other species, rank it with some of the best grasses. The small loss of weight which it sustains in drying might be expected from the nature of the substance of the grass and the loss of weight at each period is equal. The grass affords the greatest quantity of nutritive matter when in flower which makes it rank as one of those best adapted for hay.

5760. *Poa trivialis* var.  $\beta$  Host, G. A. — The proportional value which the grass, at the time of flowering bears to that at the time the seed is ripe is as 13 to 30. The proportional value which the grass of the latter month bears to that at the time of flowering, is as 6 to 15 and to that at the time the seed is ripe, as 6 to 30.

5761. *Phleum nodosum* Withers. — This grass is inferior in many respects to the *Phleum pratense*. It is sparingly found in meadows. From the number of bulbs which grow out of the straw, a greater portion of nutritive matter might have been expected. This seems to prove that these bulbs do not form so valuable a part of the plant as the joints, which are so conspicuous in the *Phleum pratense*, the nutritive powers of which exceed those of the *P. nodosum* as 8 to 22.

5762. *Agrastis vulgaris* Withers. — This is one of the most common of the weeds and likewise the earliest in these respects it is superior to all others of the same family but inferior to several of them in produce, and the quantity of nutritive matter it affords. As the species of this family are generally rejected by the cultivator on account of the lateness of their flowering, and this circumstance, as has already been observed, does not always imply a proportional lateness of foliage, their comparative merits in this respect may be better seen, by bringing them into one view as to the value of their early foliage.

	The apparent Difference of Time	The nutritive Powers		The apparent Difference of Time	The nutritive Powers
<i>Agrastis vulgaris</i>	Middle of April	128	<i>Agrastis nives</i>	Three weeks later	4
<i>var. stricta</i>	Two weeks later	92	<i>var. stricta</i>	Later date	3
<i>var. stricta</i>	Two weeks later	92	<i>var. stricta</i>	Later date	3
<i>var. stricta</i>	Two weeks later	92	<i>var. stricta</i>	Later date	3
<i>var. stricta</i>	Two weeks later	92	<i>var. stricta</i>	Later date	3

5763. *Phleum nodosum* E. B. — This species is strictly annual and from the results of this trial, its nutritive powers appear to be very inconsiderable.

5764. The grasses which afford the best culms for straw plants are according to Sinclair as follow —

For both or over soil. *Poa trivialis*, *hieracium*, and *h. strictum*, *Reberus strictus*.

Dry soils. *Cynodon dactylon*, *var. angustifolia*, *Hieracium pratense*, *Antirrhinum majus*, *Agrastis stricta*, *var. stricta*, *Reberus strictus*, and *var. stricta*, *Avena palustris*, *Poa trivialis*.

Wet soils. *Agrastis stricta*, *var. stricta*, *Reberus strictus*, *var. stricta*, *h. strictum*, *h. strictum*, *h. strictum*.

Dried grasses. Wheat, spelt wheat, rye, and oat have been sown as poor soils, and cut green and bleached but are found inferior to the above grasses for the straw plant.

5765. The period for cutting the culms is when they are in blossom. They are bleached by pouring boiling water over them, in which they remain ten minutes, and are afterwards spread on a grass-plot for seven or eight days. Sinclair found that by leaving the culms remain in hot water from one to two hours, only two or three days bleaching was required. When bleached they are taken up, washed clean and put in a moist state in a close vessel, where they are subjected to the fumes of burning sulphur for two hours. Green culms, immersed for ten minutes in a strong solution of acetic acid and then subjected to the sulphurous acid gas, are bleached perfectly white in half an hour. Green culms, immersed for fifteen minutes in muretic acid, diluted with twenty times its measure of water and then spread on the grass, become in four days as perfectly bleached as those culms which were scalded and bleached eight days on the grass. The texture of the straw was not in the least injured by these processes. The application of the sulphurous acid gas to the moistened culms, even after scalding and bleaching on the grass, had, in every instance, the effect of greatly improving the colour and that without being productive of the smallest injury to the texture of the straw. (*Hot Grass* Vol. 3d edit 467)

5765. To *plait* the *Leghorn* plait in the most perfect manner the straws should be plaited the reverse way of the common English split-stem plait. In the English plait, the straws are fastened by a small hand-mill made for the purpose; but the *Leghorn* plait has the straws worked without fastening, and pressure is applied after the plait is made. It is essential that these two points should be observed by those who wish to rival the finest *Leghorn* manufacturers. By reversing the common mode of plaiting the fingers have a much greater power in firmly and intimately knitting the straws and the round or rim fastened state of the straws allows of their being more closely knitted,—a circumstance that gives an appearance similar to the real *Leghorn* plait. (*Foot.*) The varieties of wheat or rye already mentioned (5652 and 5657) are now generally considered far preferable to any of the foreign grasses for the purpose of straw plait.

## CHAP. VII.

### *Management of Lands permanently under Grass.*

5767. In every country by far the greater proportion of perennial grass lands is the work of nature and it is not till an advanced period in the progress of agriculture that much attention is paid to their management. But as the extension of tillage, planting, and the formation of parks and gardens, limit the range of the domestic animals, their food becomes more valuable, and it then becomes an object to increase it by the culture of roots and artificial herbage on some lands, and by the improved management of the spontaneous productions of others. In a highly cultivated country like Britain, therefore, those lands retained in grass either are, or ought to be, such as are more valuable to the owners in that state than they would be in any other. Such lands naturally divide themselves into two classes—those which are fit either for mowing or pasture, and those which are fit for pasture only.

#### SECT. I. *Perennial Grass Lands fit for mowing or Meadow Lands.*

\*5768. Under the term *meadow*, we include all such land as is kept under grass chiefly for the sake of a hay crop, though occasionally and at particular seasons of the year it may be depastured by the domestic animals and we usually include under this term the notion of a greater degree of moisture in the soil, than would be thought desirable either for permanent pasture or lands in tillage. Where hay is in great demand, as near large towns, and especially if a good system of cropping is but little understood, a great deal of arable land may be seen appropriated to hay crops but the most valuable meadows are such as are either naturally rather moist, or are rendered so by means of irrigation. There are three descriptions of these meadows—those on the banks of streams and rivers; those on the uplands, or more elevated grounds; and bog-meadows and each of these kinds may be stocked with grasses, either naturally or by art, and may be irrigated by one or other of the different watering processes already described.

5769. *River-meadows*, or those which are situated in the bottoms of valleys, are in general by far the most valuable. They are the most productive of grass and hay yielding sustenance for cattle through the summer and the winter and producing an everlasting source of manure for the improvement of the adjoining lands.

5770. The soil is deep, and commonly alluvial, having been deposited by water or washed down from the adjoining mountains; the surface is even, from the same cause and, what is of considerable importance it has a gradual declivity or surface-drainage to the river or stream which almost invariably flows in the lowest part of every valley and which is essential to this description of meadow. The principal defects to which such lands are liable are, the running out of springs towards their junction with the rising lands, and the inundations of the river or stream. The former evil is to be remedied by under-draining, and the latter by embanking. Such meadows are generally stocked with the best grasses and their culture consists of little more than forming and keeping open a sufficient number of surface-gutters or furrows to carry off the rain-water—rooting out such tufts of rushes, or bad grasses and herbage, as may occasionally appear—destroying moles, and spreading the earth they throw up; removing heavy stock whenever their feet punch the surface—shutting up hush harrowing and rolling at the commencement of the growing season and finally so adjusting the mowing and pasturing as to keep the land in good heart without laying on manure.

5771. The most suitable meadows for irrigation are of this description; the necessary drains and other works are executed with greater ease and with less expense and the management, as we have seen (4380.) is also comparatively easier than in watering sloping surfaces.

5772. *Upland meadows*, or mowing lands, are next in value to those of valleys.

5773. The soil is either naturally good, and well adapted for grass, or, if inferior by nature, it is so situated as to admit of enrichment by ample supplies of manure. Of this last description are the upland meadows or hay lands of Middlesex; which though on the most tedious, and often stony clays, are yet by the abundance of manure obtained from the metropolis, rendered as productive as the best upland soils employed as hay lands. The roots of perennial grasses, whether fibrous or creeping, never strike deep into the soil; and thus, deriving their nourishment chiefly from the surface, top-dressings, or well-retained manure, repeated on the same field for centuries, form at last a thin black stratum among the roots of the grass, which produces the most luxuriant crops.

5774. The culture of upland meadows requires more attention and expense than that of valleys: being more difficult to drain and requiring regular supplies of manure. The irregular surface of uplands is apt either to contain springs or to stagnate the surface water; the first produce marsh plants and scarce herbage, and the latter destroys or weakens whatever is growing on the surface, and encourages the growth of moss. Both evils are to be remedied by the obvious resources of drainage. Moss is a very common enemy to grass lands, and is only to be effectually destroyed by rich dressings of manure. Edding, and top-dressings of lime and salt, have been recommended for destroying it; but there is no mode by

which it can be subsoiled and kept under, but by adding strength to the grass plants, and thereby enabling them to withstand their injury. Mow is never found on rich lands unless they are completely shaded by trees. Besides beds, hills, upland meadows, when neglected, are frequently troubled with ants, which soon heave or buffoons of grass and earth, more injurious and more difficult to get quit of than those of moles. The mode of taking moles is a simple operation, and will be described in the proper place; that of destroying ants is more complicated and tedious, and, being peculiar to grass lands, shall here be described.

**5774. Ant hills, or hekatations, are injurious to meadow lands, by depriving the farmer of a crop in proportion to the surface they occupy and by interfering with the operations of rolling and mowing. They consist of little eminences, composed of small particles of sand or earth lightly and artfully laid together which may often be computed at a tenth part, or more, of old grass-lands. In some places, where negligence has suffered them to multiply almost half the land has been rendered useless: the hills standing as thick together as grass-sticks in a hay field and what is very surprising this noxiousness is defended by some, who affirm, that the area or superficies of their land is thereby increased, whereas it is well known that very little or no grass ever grows thereon, and therefore, if the surface is increased, the produce is proportionably decreased.**

**5775. In order to remove ant-hills, and destroy the insects, it has been a custom in some places, at the beginning of winter and often when the weather was not very cold, to dig up the ant-hills three or four inches below the surface of the ground, and then to cut them in pieces, and scatter the fragments about; but this practice only disseminates the ants, instead of destroying them as they hide themselves among the roots of the grass for a little time, and then collect themselves together again upon any little eminence of which there are great numbers ready for their purpose, such as the circular ridges round the hollows where the hills stood before. It is, therefore, a much better method to cut the hills entirely off rather lower than the surface of the land and to let them lie white at a little distance, with their bottom upwards by this means the ants, which are known to be very insidious of their abodes, continue in their habitations until the rains by running into the r holes of communication, and stagnating in the hollows formed by the removal of the hills, and the frosts, which now readily penetrate, destroy them. If a little soil were thrown on the places, and washed in with the rains, it would probably contribute greatly to the intended effect. The hills, when rendered mellow by the frosts, may be broken and dispersed about the land. By this method of cutting the hills, one other advantage is gained: the land soon becomes even and fit for mowing, and the little eminences being removed, the insects are exposed to the wet, which is very disagreeable and destructive to them. It would, perhaps, be a better practice than that of scattering the hills to remain on the ground, to collect the parts of them which have been pared off into a heap, in some convenient place, and then turn them into a compost, by mixing a portion of quick lime with them. In wet weather these insects are apt to accumulate heaps of sandy particles among the grass, called by labourers upstart-hills, which quickly take off the edge of the scythe. These hills which are very light and compressible, may be conveniently removed by frequent heavy rolling.**

**5776. In the Norfolk mode of cutting and burning ant hills, the process is, to cut them up with a heart-shaped sharp spade or shovel, in irregular lumps of from ten to fifteen inches in diameter and from two to five or six inches thick. These are to be turned the grass side downwards, until the mould side is thoroughly dry, and then to be set the grass-side upwards, until they are dry enough to burn. The fire may be kindled with brushwood, and kept smothering, by laying the rods or lumps on gradually as the fire breaks out, until ten or fifteen loads of ashes are raised in one heap, which the workmen formerly completed for a shilling or eighteen pence each load of ashes. The places from which the hills have been removed may be sown with grass-seeds. Besides the destruction of the ants, this is a ready though by no means an economical, way of raising manure, and in some cases ought not to be neglected, on grounds where such a process is common.**

**5777. What is called "guiding" ant-hills is thus described. — With a turning-iron make two cuts across the hill at right angles to each other then turn back the four quarters thus obtained from off the hill, leaving it bare next cut out and throw to a distance the interior earth of the hill with all the ants turning their winter's board of provision, as well as all their excavated abode, to the very bottom. Now return the quarters of turf to their former place, tramping them down to form a basin to hold the winter's rain, which will prevent the settlement of any new colony of the ants, and they being thrown on the surface, will perish by the frost.**

**5778. Where grass lands are sufficiently rolled with a heavy roller once or oftener every year no ant-hills will ever be formed greater than the roller can compress, and consequently no injury will be sustained. In this, as in most other cases of disease, proper regimen is the best cure. In domestic economy various directions are given for destroying bugs, lice and other vermin but who ever had any to destroy who attended properly to cleanliness?**

**5780. The surface of some grass lands that have been long rolled is apt to get into that tenacious state denominated lide bound. When this is the case scarifying the turf with a plough consisting only of coulter, or harrow teeth, or in preference to all other implements, with Wilkie or Kirkwood's braker, so that the whole surface may be cut or torn, is to be recommended. That tenacious state rolling tends to increase whereas, by scarifying, the surface is loosened, and the roots acquire new means of improved vegetation. This operation seems particularly useful, when it precedes the manuring. When hay land of a retentive quality is depastured by cattle or horses in wet seasons, it receives much injury from their feet, and becomes what is technically called poached. Every step they take leaves an impression, which fills with rain water and then the hole stands full like a cup. This wetness destroys the herbage not only in the hole, but that also which surrounds it, while at the same time the roots of the grasses, as well as the ground, are chilled and injured. No good farmer therefore, will permit any cattle to set a foot on such land in wet weather and few during the winter months, on any consideration. Sheep are generally allowed to pasture on young grasses in dry weather from the end of autumn to the beginning of March they are then removed, and it rarely happens that any animal is admitted till the weather be dry and the surface so firm as to bear their pressure without being poached or injured.**

**5781. In manuring upland meadows, the season, the sort, the quantity and the frequency of application are to be considered.**

**5782. With regard to the season at which manure should be applied, a great difference of opinion prevails among the farmers of England. In the county of Middlesex, where almost all the grass lands are preserved for hay the manure is invariably laid on in October (*Middlesex Reports*, p. 24.) while the land is sufficiently dry to bear the driving of loaded carts without injury had when the heat of the day is so moderate as not to scald the delicate parts of the dung. Others prefer applying it immediately after the hay-time, from about the middle of July to the end of August, which is said to be the "good old time" (*Annals of Agriculture* vol. iv p. 138), and if that season is inconvenient, any time from the beginning of February to the beginning of April. (*Dickson's Practical Agriculture* vol. i, p. 915.) It is, however, too common a practice to carry out the manure during frosty weather when, though the ground is not cut up by the carts, the fertilizing parts of the dung are disengaged, and washed away by the snow and rain before they can permeate the soil.**

**5783. There is scarcely any sort of manure that will not be useful when laid on the surface of grass grounds but, in general, those of the more rich dung kinds are the most suitable for the older sort of round lands; and dung, in comparison with fresh vegetable earthy substances, the most useful in the new lays or grass lands. In Middlesex it is the practice of the best farmers to prefer the richest dung they can procure, and seldom to mix it with any sort of earthy material, as they find it to answer the best with regard to the quantity of produce, which is the principal object in view the cultivators depending chiefly for the**

sale of their hay in the London markets. It is the practice to turn over the dung that is brought from London in a tolerable state of rotteness, once chopping it well down in the operation, so as to be in a maddling state of ferment when put upon the land. It is necessary, however, that it should be in a more rotten and reduced state when applied in the spring than when the manure is chosen for that purpose. (*Dickson's Practical Agriculture*, vol. ii. p. 916.)

5784. Some interesting experiments have been made with different kinds of manure, for the purpose of ascertaining their effects, with regard to the quantity and quality of the produce on different kinds of land. Fourteen lots, of half an acre each, were thus manured, and the grass was made into hay all as nearly alike as possible. The greatest weight of hay was taken from the lot manured with horse, cow and slaughterhouse dung, all mixed together of each about an equal quantity. It lay in that state about two months; and was then turned over and allowed to lie eight or ten days more, after which it was put on the land before it had done fermenting, and spread immediately. To ascertain the quality of the produce of the different lots, a small handful from each was laid down on a dry clean place, where there was little or no grass, and six horses were turned out to them one after another. In selecting the lots, there seems to have been little difference of taste among the horses, and all of them agreed in rejecting two lots, one of which had been manured with blubber mixed with soil, and the other with soot, in both instances laid on in the month of April preceding. (*Lancashire Report*, p. 130. & seq.)

5785. The proportion of manure that is necessary must, in a great measure, depend upon the circum- stances of the land, and the facility of procuring it. In the district of London where the manure is of a very good and enriching quality, from its being produced in stables and other places where animals are highly fed, the quantity is usually from four or five to six or seven loads on the acre, such as are drawn by three or four horses, in their return from taking up the hay to town. (*Dickson's Pract. Agr.* vol. ii. p. 916.)

5786. Manure is laid on at intervals of time more or less distant, according to the same circumstances that determine the quantity of it. Though there are some instances of hay grounds bearing fair crops every year during a length of years, without any manure or any advantage from pasturage, except what the after-grass has afforded (*Marshall's Review of Reports to the Board of Agriculture* p. 163. *Western Department*); yet, in general, manure must either be allowed every third or fourth year in the land depastured one year and mown the other, or what is better depasture two years, and mow the third. (*Northumberland Report* p. 111.) A succession of hay crops without manure, or pasturage, on meadows not irrigated, is justly condemned by all judicious farmers, as a sure means of impoverishing the soil.

5787. Bog meadows are the least valuable of any they are of two kinds peat bogs, and earthy bogs.

5788. Peat bogs are situated in hollows or basins, which from having no natural outlet for water and not being so deep or so plentifully supplied with that element as to constitute lakes, become filled up with aquatic plants and mosses. By the decay of these after a certain time, and the drainage and culture of art a surface of mossy soil is formed on which some of the inferior grasses may be sown or will spring up naturally. In warm moist climates, and where the mould of the bog is rich loam or Timothy grass may be found to answer but in general the woolly soft grass and cock-foot are resorted to, unless loaded lime be applied, or a coating of sand or earth, in which cases the clovers and better grasses will sometimes answer. These bogs are in general too soft for pasturing any other animals than sheep.

5789. Earthy bog meadows are situated either in hollows or on slopes. They are formed by an accumu- lation of water in the subsoil which not finding a free passage in any one point spreads under and distends upwards through a considerable extent of surface. The grasses on such meadows before they are drained are chiefly of the sprot or Venus kind; but by draining the quality of these is improved, and better kinds appear. Such meadows yield a considerable produce of coarse hay they abound chiefly in cold hilly districts devoted to breeding.

5790. The culture and management of bog meadows differ in nothing essential from those of the river kinds. A lighter roller is used in spring the greatest care is taken in cutting down the latter grass, whether with small cattle or sheep and in some cases, in very dry weather in summer the main drains are dammed up for a few weeks in order to stagnate the water and supply the soil with moisture. No manure is ever given unless in the case of some cultivated peat bogs, which are dressed with earthy or saline mixtures.

5791. As branches of culture common to every description of hay lands may be men- tioned, the hay making, the application of the after-grass, and pasturage.

5792. The making of natural or meadow hay has been carried to greater perfection in the neighbourhood of London than any where else and it may therefore, with great propriety, be recommended as an example to the rest of the kingdom. The following account of it is drawn from *Middleton's Agricultural Survey of Middlesex*

5793. When the grass is nearly fit for mowing the Middlesex farmer endeavours to select the best mowers, in number proportioned to the quantity of his grass and the length of time it would be advisable to have it in hand; which having done, he lets it out, either as piece-work, or to be mown by the acre. In the latter way each man mows from one acre and a half to an acre and three quarters per day some there are who do two acres per day during the whole season. About the same time he provides five hay makers (men and women, including loaders, pitchers, stackers, and all others) to each mower. These last are paid by the day the men attending from six till six, but the women only from eight till six. For an extra hour or two in the evening, when the business requires despatch they receive a proportionate allowance.

5794. The mowers usually begin their work at three, four or five o'clock in the morning, and continue to labour till seven or eight at night; resting an hour or two in the middle of the day. Every hay-maker is expected to come provided with a sick and a rake of his own; nevertheless, when the grass is ready and labourers scarce, the farmer is frequently obliged to provide both but for the most part only the rake, Every part of the ground is cut in order, except clearing the ground which is done with rakes; and loading the carts, which is done by hand.

5795. First day. All the grass mown before nine o'clock in the morning is dried, is taken thoroughly to pieces, every lump, and is thrown evenly over all the ground. The regular method of loading grass for hay the hay will be of a more valuable quality than mown usually in the stack, and will consequently last longer in the stack, and will be of greater quantity when cut into straw, and will be sold at a better price; for when the grass is suffered to lie dry or even before it is loaded out of length of time, the moisture is dried by the sun and wind, and the inferior part is not dried, but withered, so that the horses lose much, both as to quality and quantity, which goes after other circumstances. Here after the loading is finished, the hay is spread with the same degree of care and attention; and if, from the nature of the hay, they are able to turn the whole again they do so, or at least of much of it as they can, till twelve or one o'clock, at which time they stop. The first thing to be done after dinner is to rake it

into what are called single wind-row; and the last operation of this day is to put it into grass-cakes.

5796. Second day. The business of this day commences with turning all the grass that was mown the first day after nine o'clock, and all that was mown this day before nine o'clock. Next the grass-cakes are to be well shaken and laid out (or separate piles) of five or six yards' diameter. If the crop should be so thin and light as to leave the spaces between these stacks too large, such spaces must be immediately rolled close, and the rakes mixed with the other hay in order to fill all drying. A uniform colour. The main business is to turn the stacks, and after that, to turn the ones that were loaded in the first part of the morning, once or twice, in the manner described, the first day. This should all be done before twelve or one o'clock, and then the whole may lie to dry while the work-people are at dinner. After dinner, the first thing to be done is to take the stacks into double wind-row; next, to

min the grass into single wind-rows; then the double wind-rows are put into double wind-rows; and lastly the double wind-rows are put into grass-mounds. This completes the work of the second day.

**5797. Third day.** The grass mounds are not spread on the second day, and then that mounds in the early part of this day, it is sent to be tacked in the morning, and then the grass-mounds are to be spread into two or three, and the highest ends into sections of four mounds. These smaller mounds, though last spread, are that cannot, then those which were in grass-mounds; and sent this grass is mowed once or twice before mowing or mowing, when the mowing is done as usual. If the weather has proved sunny and then the hay which was last night in grass-mounds with this exception is in a proper state to be carted; but if the weather should, on the contrary have been

cool and steady, as part of it probably will be fit to carry. In that case, the last night's mowing should be done in a row and which was in grass-mounds last night should be done; then the grass which was last night spread from the sections into double wind-rows. After this, the hay which was last night in double wind-rows, is made up into single wind-rows, and sent to be tacked the day or night, and also to put the rebuffs upon the top of each cart. Next, the double wind-rows are put into double wind-rows, and the single wind-rows into grass-mounds, as on the preceding day.

**5798. Fourth day.** On this day the great cocks, but mowed, are usually carted before dawn. The other operations of the day are such, and in the same order as before described, and the continued daily work the hay harvest is completed.

**5799. As general rules,** the grass should, as much as possible, be protected both day and night, against rain and dew by covering. Care should also be taken to proportion the number of hay-makers to that of the mowers, so that there may not be more grass in hand at any one time than can be managed according to the foregoing process. This proportion is about twenty hay-makers (of which number twelve may be women) to four mowers; the latter are sometimes taken half a day to mow the former. But in hot, windy or very drying weather a greater proportion of hay-makers will be required than when the weather is cloudy and cool. It is particularly necessary to guard against spreading more hay than the number of hands can put into cocks the same day or before rain. In showery and uncertain weather the grass may sometimes be suffered to lie three, four, or even five days in swath, but before it has lain long enough for the under side of the swath to become yellow (which, if suffered to lie long, would be the case) particular care should be taken to turn the swaths with the heads of the rakes. In this state, it will cure so much in about two days, as only to require being tacked a few hours when the weather is fine, previously to its being put together and carted. In this manner hay may be made and put into the stack at a small expense, and of a moderately good colour but the tops and bottoms of the grass are insufficiently separated by it.

**5800. The hay-tacking machine** has been invented since Middleton described the hand process as above. This machine (*fig. 574*) is found to be a most important saving of manual labour. It is computed that a boy and horse with the machine will do as much in an hour as twelve or fifteen women. The hay rakes, which may be added to the same axle when the tacker is removed, is also an equal saving, and a requisite accompaniment to it; as where few or no women are kept for tacking, there must necessarily be a deficiency of rakers; and these machines are coming into general use near London, where the price of manual labour is high and hands sometimes scarce. They are also finding their way among the proprietors of extensive parks in all parts of the country as saving much labour in making hay from natural pasture.

**5801. There are no hay-stacks** more neatly formed, nor better secured, than those made in Middlesex. At every vacant time, while the stack is carrying up, the men are employed in pulling it, with their hands, into a proper shape; and, about a week after it is finished, the whole roof is properly matched and then secured from receiving any damage from the wind, by means of a straw rope, extended along the eaves, up the ends, and on each side of the ridge. The ends of the thatch are afterwards cut evenly below the eaves of the stack, just of sufficient length for the rain-water to drip quite clear of the hay. When the stack happens to be placed in a situation which may be suspected of being too damp in the winter a trench of about six or eight inches deep, is dug round and nearly close to it, which serves to convey all the water from the spot, and renders it perfectly dry and secure.

**5802. During the hay harvest** it is of great advantage to the farmer to give constant personal attendance on every party directing each operation as it goes on. The man who would cure his hay in the best manner and at a moderate expense, must not only urge the persons who make the hay the men who load the waggons, and those who make the stack but he should be on the alert, to contrive and point out the manner in which every person may do his labour to the most advantage. Unless he does this, one moiety of the people in his hay field will be of no material use to him, and if he should be absent for an hour or more, during that time little or nothing will be done. The farmers of Middlesex engage many hay-makers some of them have been known to employ two or three hundred, such men find it necessary to be on hand, and the work-people find them sufficient employment. A man of energy will make the most of every hour, and secure his hay while the sun shines; one of an opposite description keeps his time away, and suffers his hay to be caught in the rain, by which it is frequently half spoiled. Or if the latter should have the good fortune of a continuance of dry weather his hay will be a week longer in the field than his neighbour's and the sap of it dried up by the sun.

**5803. The waste of grass, on being dried into hay,** is supposed to be three parts in four by the time it is laid on the stack. It is then further reduced by heat and evaporation; in about a month, perhaps one twentieth more, or 60 lb. of grass are reduced to 28 lb. of hay and between that and 30 it continues through the winter. From the middle of March till September the operations of trading and marketing expose it so much to the sun and wind, as to render it considerably lighter probably 30 that is, hay which would weigh 80 the instant it is separated from the stack, would waste to 50 (in trading, exposure on the road, and at market for about 34 hours) by the time it is usually delivered to a purchaser. During the following winter the waste will be little or nothing. It is nearly obvious, that the same hay will weigh on delivery 30 in summer and 30 in winter. From this circumstance and others which relate to price, a farmer may determine what season of the year is the most advisable for him to sell his hay.

**5804. In making the hay of hay meadows** considerable care is requisite both from the inferiority of the climates where such bogs abound, and from the nature of the grasses they produce. In some cases, the grass is of so soft a quality that it is difficult to convert it into hay. To prevent its being consolidated in the cocks, it must be frequently opened up, and when the weather permits, completely exposed to the sun and wind, this sort of grass being only capable of sustaining a very moderate degree of fermentation.

**5805. When the natural herbage is of a coarser description,** it may be put into small cocks, in rather a green or damp state so as to go through the progress of "a sweating" or slight fermentation. The woody fibres in coarse hay are thus rendered more palatable and nutritious, while its condition for becoming fodder is considerably improved but when any warmth becomes perceptible, if the weather will permit, the hay should be spread out, and put into large cocks, the moment it is in a dried state.

**5806. In the winter seasonal districts, in the north-west parts of Scotland, hay-barns,** it is thought by some, would be advantageous the construction should be as open as possible for the purpose of drying, as well as of preserving the hay. In some of these districts a curious device has been fallen upon of making the dried hay into ropes of two fathoms in length, and then twisted twofold. Being thus compressed, less room is required in the barn and in this shape it is carried, with greater facility to distant places, for the use of cattle during stormy weather.

**5807. In making Scotch hay** (if hay it may be called, which is never dried) it is usually cut and put into small cocks, from which it is commonly taken as wanted. When it is to be put into larger cocks, it must be proportionally better dried. The stoniness of this grass being remarkably vivid, cannot easily be so dried as to admit of stacking in large bodies.

**5808. The sowing of hay, at the time of stacking** has been practised in Derbyshire and in the North Riding of Yorkshire. The aim, particularly when sown in the crop of roots, or when the first crop has received much rain, objects the fermentation and prevents moulding. If straw is mixed with the hay the heating of the stack is still further prevented, by the straw imbibing the moisture. Cattle will eat, not only such sown hay but even the straw mixed with it, more eagerly than better hay not sown, and

will also thrive as well upon it. The quantity recommended is, a peck of salt to a ton of hay. By this application, hay that had been soaked was preferred by cattle to the best hay that had not been altered.

5806. *To make hay-tee.* Roll at the rate of a handful of hay to three pailons of water, or, if the water be poured boiling hot on the hay it will answer nearly as well. Give it to the cattle and horses to drink when cold or if the cattle and horses are anywise ill, and under cover, give it to them blood-warm. This drink is so extremely nutritive, that it nourishes the cattle astonishingly, replenishes the udders of the cow with a prodigious quantity of milk, makes the horse stale plentifully, and keeps him healthy and strong and by this method one trust or hundred of hay will go as far as eight or ten would otherwise do. The cattle and horses do not seem to like it at first, but if they are kept till very thirsty, they will drink freely of it ever afterwards. The hay after being used as before mentioned and dried, may be used as litter for horses and cattle. It will make very good manure, and save straw, which is a considerable advantage, especially where there is a scarcity of that article. (*Devil's Rap. of Wills.*)

5810. *The after-grass on all meadows is generally fed off* on firm lands, and in the dry season, by either sheep or heavy cattle but in the winter only by sheep, unless the soil is so dry as not to be injured by the feet of cows or horses. The feet of the latter are much less injurious than those of the former but their bite being closer is more apt to tear up the plants, than the bite of the horned tribe.

5811. *Cattle are generally removed from meadow-lands in Middlesex in November; horses in the month following and sheep allowed to remain till February.* In Lincolnshire, Leicestershire, and on many river-meadows, every description of stock is allowed to remain till April, and sheep till May. In some districts, the whole of the after growth is preserved from every species of stock till the following May, when it is fed off with sheep but this greatly retards the hay crop for that year. It is evident that a good deal must depend on the farmer's other resources for keep for his stock.

5814. *The after-grass, where manure is very abundant* is sometimes mown and made into hay or rotten a sort and not very nutritive food, given to cows or sheep; but this is reckoned a bad practice, even in the neighbourhood of London, where manure may be had in abundance. It is also the usage of some to leave the after-grass on the ground without being eaten till spring when it is said to be preferable, for ewes and lambs to turnips, cabbages, or any other species whatever of what is termed spring-feed. This mode of management, which is strongly recommended by Young, and in some cases by Marshall also, is unknown in the north where, though it is, in many instances, found beneficial with a view to an early spring growth, not to eat the pasture too close before winter it would be attended with a much greater loss of herbage, than any advantage in spring could compensate, to leave the after growth of mown grounds untouched till that season.

5818. *A system of alternate mowing and feeding is practised on some hay lands, partly to save labour and manure, and partly to subdue mosses and coarse grasses.* On some soils even rich grass lands, when annually mown, become subject to weeds for it tends to encourage moss, and gives advantage to the stronger rooted grasses, which gradually change and deteriorate the nature and quality of the herbage. The bottom becomes thin, the white clover disappears, and coarser plants occupy the ground. When this takes place the pasture should be fed, instead of being mown for the space of two or three years, until the weeds have been subdued, and the finer grasses re-appear.

5814. *By adopting the plan of mowing and feeding alternately,* a farmer it is said, may go on longer without the application of manure, but his fields, in the end, will be ruined by it. It is contended, that to maintain a proper quantity of stock, the land must be accustomed to keep it, particularly in the case of sheep that where land has been used to the system if manured for pastures, it will often produce more grass, but that grass will not (*setaria perennis*) support so much stock, nor fatten them nearly so well and that old pasture will not produce so much hay as land that has been constantly mowed for such will grow best as it has been accustomed to grow and will not readily alter its former habits. On the other hand it is asserted that many experienced farmers prefer the system of feeding and mowing alternately as they find that, under that system, the quality and quantity of the hay have been improved and the pasturage, in the alternate year has been equally sweet and productive.

## SECT. II. Permanent Pastures

5815. *Permanent pastures* may be divided into two kinds rich or feeding lands and hilly or rearing pastures. Under the former, we may comprehend all old rich pastures capable of fattening cattle and under the second, such as are only adapted to rearing them, or are more advantageously depastured with sheep.

### SUMMER 1. Rich or feeding Pastures.

5816. *Feeding pastures* may include such as are equally fit for hay lands, or for being converted to arable husbandry their characteristic being, that they are used for feeding stock, and keeping working animals and milch cows in good condition. We mentioned in a former chapter that pasturage for one year or for two, or more is frequently interposed in the course of cropping arable land, to prevent that exhaustion of the soil which is commonly the consequence of incessant tillage crops. The same culture and management recommended here for rich grass lands are equally applicable to them there being no difference except that the latter are generally considered less suitable than rich old turf for fattening heavy stock such as large oxen.

5817. *The culture and management of feeding pastures,* whether of a few years, or of perpetual duration, may be considered in regard to those necessary operations already noticed under the former section such as the extirpation of weeds and noxious shrubs, clearing away ant and mole-hills, the application of manure, the time of stocking, the number of the animals and whether all should be of one or of different species, &c. the extent of the enclosures, and the propriety of eating the herbage close or leaving it always in a rather abundant state all these are questions which it is scarcely possible to decide in a satisfactory manner, by the application of general rules. They can only be solved,

with any preparation to utility, by a reference to the particular circumstances of each case; for the practice of one district, in regard to these and other points, will be found quite inapplicable to others where the soil and climate, and the purposes to which the pastures are applied, are materially different.

5818. The weeding of pastures should be regularly attended to. Weeds in pastures injure the farmer by the ground they occupy, the seeds they disperse, and sometimes, by influencing the quality of milk, or the health of the cattle.

5819. On the large scale of a farm small creeping weeds cannot be removed but large perennial plants, such as the dock, fern, nettles, and biennial, such as the thistle, and ragweed together with rushes and coarse tufts or tussocks of tall oat-grass, should never be permitted to shoot up into flower. The dock ought to be taken out by the root with the dock-weeder and the others cut over with spades or spuds. Nettles may be mown over as may some other weeds, and some descriptions of rushes; fern is most effectually killed by bruising or twisting under the stem, when the frond or herb is nearly fully expanded. Smaller weeds may be mown and this operation should never be deferred later than the appearance of the flowers. Where the sloe-thorn forms part of the enclosure hedges, or the English elm, hawthorn, and some other trees, grow in or around the field, they are apt to send up suckers these should be pulled up, otherwise they will soon become a serious nuisance. In some parts of England, especially in the central districts, the hedge wastes, from the spread of the sloe-thorn and creeping rose (*Rosa arvensis*) are sometimes six or ten yards in width.

5820. To prevent the growth of mosses is one of the greatest difficulties in the management of old pasture land; by them the finer species of grasses are apt to be overwhipped, and the coarse sorts only remain. Drainage, and the use of rich composts, are in this case necessary. Harrowing and cross harrowing with a common harrow or with what are called grass harrows (fig. 795.) which go from one to two inches

795

deep, with a sprinkling of grass-seeds afterwards, and some lime or well prepared compost, are the most likely means of destroying the moss, and improving the pasture. Feeding sheep with oil-cake, and allowing them to pasture on the land, has also been found effectual for the destruction of moss, and bringing up abundance of grass. But the radical remedy is to plough up such grass lands upon the first appearance of moss, or before it has made any considerable progress and sow them with corn.

5821. The removal of ant and mole hills should be attended to during the whole summer. The manner of destroying ants has already been described. Mole-hills spread on grass lands may be considered as of service rather than otherwise. These operations, together with weeding, and spreading the manure dropped by the larger stock should go on together at intervals during the whole summer.

5822. The application of manures to grazing lands, which not being used as hay grounds afford no means of supply may certainly be considered a preposterous practice, and one that must be ruinous to the other parts of a farm.

5823. In the Code of Agriculture it is nevertheless stated, that "to keep grass in good condition, a dressing of from thirty to forty cubic yards or cart-loads of compost is required every four years. The application of unmanured pasturemanure will thus be rendered unnecessary, which ought at least to be avoided, in meadows appropriated for the feeding of dairy cows, from its affecting the quality of the milk." (p. 476.) Grass lands kept at an expense of this kind will seldom, it is believed, be found to remunerate a farmer sufficiently. The same thing is recommended (probably from inadvertence or mere following the track of preceding writers) in *Dickson's Practical Agriculture* vol. II. p. 263. But, except the dung dropped by the pasturing animals, which should always be regularly spread from time to time, it may be laid down as a rule of pretty extensive application, that if grass lands do not preserve their fertility under pasturage, it would be much better to bring them under tillage for a time, than to enrich them at the expense of land carrying crops of corn. (*Sup. Sec. Art. Agr.*)

5824. Trampling or stacking on the field, or carrying to be consumed there during winter the provender that ought to have furnished disposable manure for the use of the farm at large, is another practice not less objectionable. It is to no purpose that such a wasteful practice is defended on dry light soils, which are alleged to be thus benefited by the trampling of the cattle. (*Marsden's Rural Economy of Yorkshire*, vol. II. p. 131.) During the frequent and heavy falls of rain and snow in winter there is scarcely any land so dry as not to be injured by the trampling of heavy cattle and were there any thing gained in this respect by this management, it would be much more than counterbalanced by the loss of a great part of the manure, from the same cause. The able writer to whom we have just now referred very properly disapproves of carrying on manure in winter; and for the same reason, namely, the loss of it, which must necessarily be the consequence, he ought to have objected to studding on the land, or treading it at that season. The practice, however is but too common in those districts, both in South and North Britain, where the knowledge of correct husbandry has made but little progress. It is equally objectionable whether the fodder is consumed on meadows where it grows, or on other grass lands. The fodder should, in almost every instance, be eaten in houses or fold-yards, instead of the dung being dropped irregularly over the surface; or, at least to be gathered the once, accumulated in some spots sheltered by trees and hedges, to which the animals necessarily resort during the storms of winter.

5825. The time of stocking pastures in spring must evidently be earlier or later, according to the climate, and in the same climate according to the season, and the state of

growth, which it is desirable that the grass should attain before being stocked, must in some degree be determined by the condition and description of the animals to be employed in consuming it, whether they are only in a growing state or approaching to fatness, whether milch cows or sheep, or a mixture of animals of different species. It conveys no very precise idea respecting these points, though the remark itself is just, to say that the herbage should not be allowed to rise so high as to permit the earner plants to run to seed and that it is bad management to suffer store stock to be turned upon a fall bite. (*Marshall's Yorkshire*, vol. ii. p. 129.)

5825. *The great object to be aimed at* is, that the stock, of whatever animals it may consist, should be carried forward faster or slower according to the purposes of their owner and that no part of the herbage should be allowed to run to waste, or be unprofitably consumed. But nothing but careful inspection of the land and of the stock, from time to time can enable any grazer to judge with certainty what are the best measures for attaining these objects. "Feeding cattle" says Marshall "which are forward in flesh, and are intended to be finished with grass, may require a full bite at first turning out; but for cows, working oxen and rearing cattle, and lean cattle intended to be fatted on grass, a full bite at the first turning out is not requisite. Old Lady-day to the middle of April, according to the progress of spring, appears to me, at present, as the best time for shutting up mowing grounds and opening pastures." (*Marshall's Yorkshire* vol. ii. pp. 154, 155.)

5827. *In regard to the state of the growth of pastures when first stocked* some distinction should be made between new leys and old close swards. To prevent the destruction of the young plants, whether of clover or other herbage, on the former description of pasture, which would be the consequence of stocking them too early, especially with sheep, they should be allowed to rise higher than would be necessary in the case of old turf and to secure their roots from the further injury of a hot summer it is advisable not to feed them close in the early part of the season, and probably not at any time throughout the whole of the first or second season, if the land is to be continued in pasture. The roots of old and firm sward, on the other hand, are not in so much danger either from close feeding or from the heats of summer and they are in much less danger from the frosts and thaws of winter.

5828. *With regard to the stock which should be employed*, all souls rather moist and of such a quality as is the case with rich clays, as to produce herbage suited to the fattening of cattle, will, in general be more advantageously stocked with them than with sheep but there can be no other rule for the total exclusion of sheep, than the danger of the rot nor any other general rule for preferring one kind of stock to another, than their comparative profits. (*Sup. art. Agr*)

5829. *Whether the stock should be all of one or of different kinds* is another question to be discussed.

5830. *With regard to a mixed stock*, the sentiments and practice of the best graziers seem to be in its favour. "It is generally understood that horses and cattle intermixed will eat grass cleaner than any species will alone, not so much from their separately affecting different grasses, as from the circumstance of both species dilkling to feed near their own dung." (*Marshall's Yorkshire*, vol. ii. p. 154.) "Some few graziers follow the old custom of keeping only one kind of stock upon the same ground, whilst others we think, with more propriety intermix with oxen and cows a few sheep, and two or three colts in each pasture, which both turn to good account, and do little injury to the grazing cattle. In some cases sheep are a real benefit, by eating down and destroying the ragwort (*Sanicula Jacobina*), which disfigures some of the best pastures of the county, where oxen only are grazed." (*Northumberland Report* p. 126.) In Lancashire, where grazing is followed to a great extent, and with uncommon success, as well as in most other districts, the practice seems to be almost invariably to keep a mixed stock of sheep and cattle on the same pasture (*Lincolnshire Report*, p. 174) in proportion varying with the nature of the soil and the quality of the herbage.

5831. *To estimate the number of animals that may be depastured on any given extent of ground* is obviously impossible, without reference to the particular spot in question and the same difference exists with regard to the propriety of feeding close, or leaving the pastures rough, that prevails in most other parts of this subject. Though there is less in stocking too sparingly the more common and dangerous error is in overstocking, by which the summer's grass is not unfrequently entirely lost. On rich pasture lands in the neighbourhood of Banbury in Oxfordshire, one ox and two sheep are calculated as stock sufficient for one acre.

5832. *With respect to the use of enclosures*, small fields are much to be preferred to large ones, for heavy stock.

5833. *Besides the advantages of shelter* both to the animals and the herbage, small fields enable the grazer either to separate his stock into small parcels, by which means they feed more at their ease, or to give the best pastures to that portion of them which he wishes to come earliest to market. The advantages of moderate-sized enclosures are well known in the best grazing counties but the subdivisions are in some instances much more minute than is consistent with the value of the ground occupied with fences, or necessary to the improvement of the stock. In all cases, says Marshall, where feeding cattle or dairy cows make a part of the stock, and where situation, soil, and water will permit, every sort of grazing grounds ought, in my idea, to consist of three compartments one for head stock, as cows or feeding cattle; one for followers, as rearing and other lean stock; and the third to be shut up to freshen for the leading stock. (*Marshall's Yorkshire*, vol. ii. p. 153.)

5834. *Large enclosures* are in general best adapted for sheep. These animals are not only impatient of heat and liable to be much injured by it, in small pastures often surrounded by trees and high hedges, but they are naturally, with the exception perhaps of the Leicester variety, much more restless and easily disturbed than the other species of live stock. "Sheep," says Lord Kilmore, "love a water ragg, and ought to have it; because they delight in short grass give them gently or slowly water, and any fence will keep them in. confine them to a field of seven or eight acres, and it must be a very strong fence that keeps them in." (*Devonshire Farmer* p. 203.) Though fields so large as eighty or ninety acres can be advisable only in hilly districts, yet the general rule is nevertheless consistent with experience, in regard to all our best domesticated varieties.

5835. *With respect to the propriety of eating the herbage close, or leaving it rather in an abundant state*, an eminent agriculturist observes, that there seems to be a season, some time during the year, when grass lands, particularly old turf, should be eaten very close,

not merely for the sake of preventing waste, but also for the purpose of keeping down the coarser kinds of plants, and giving to the pastures as equal and fine a sward as possible.

5836. The most proper period must partly depend upon the convenience of the grazer; but it can hardly be either immediately before the drought of summer or the frost of winter. Some time in autumn, when the earliest heat of the season is over, and when there is still time for a new growth before winter may be most suitable for the land itself, and generally also for the grazer, his fat stock being then mostly disposed of, or carried to the after-grass of mown grounds. The sweeping of pastures with the scythe may be employed as a substitute for this close feeding the waste and labour of which, however though but trifling, it does not seem necessary to incur on rich grazing lands, under correct management. (*Ann. & Mag. Nat. Agr.*)

5837. *Wintering pastures* is a practice which is sometimes adopted in districts where there is a scarcity of winter food. Under that system, fields in pasture are shut up early in May, and continued in that state till November or December when the farmer's stock is turned in, and continue to pasture till the May succeeding. Such management, however, can only be advisable on a soil of the driest nature, which will not be injured by poaching in the wettest seasons. It is practised in a few places in Cardiganshire; but is considered by the late Thos. Jones, Esq., of Hafod, as the result of necessity the farmers not being able to bring sufficient stock to eat it down in season, when its nutritive powers are in their best state.

5838. Water should be provided for every field under pasture and also shelter and shade, either by a few trees, or by a portable shed, which may be moved with the stock from one enclosure to another. Where there are no trees, rubbing posts are also found a desirable addition. In Germany they have portable sheds which are employed both in summer and winter and generally with a piece of rock-salt fixed to a post for the cattle to suck at. (*Fig 796.*)

#### SECTION 2 *Hilly and Mountainous Pastures.*

5839. *Hilly pastures* include such low hills as produce fine short herbage and are with much advantage kept constantly in pasture, though they are not altogether inaccessible to the plough as well as such tracts as, from their acclivity and elevation, must necessarily be exclusively appropriated to live stock. The former description of grass lands, though different from the feeding pastures, of which we have just treated, in respect to their being less convenient for tillage management, are nevertheless in other circumstances so nearly similar as not to require any separate discussion. These low hills are for the most part occupied with sheep, a very few cattle being sometimes pastured towards their bases and they frequently comprise herbage sufficiently rich for fattening sheep, together with coarser pastures for breeding and rearing them.

5840. In regard to the management of upland pastures, of the rules which judicious farmers practise, the following deserve to be selected —

5841. To enclose those pastures, at the same extent of land, when sheltered and properly treated, will feed a greater quantity of stock, and to better purpose, than when in an open and exposed state. Not to overstock upland pastures; for when this is done, the cattle are not only starved, and the quantity of herbage diminished, but the soil is impoverished. When the pasture ground is enclosed and subdivided, so as to admit of it, the stock ought to be shifted from one enclosure to another at proper intervals giving the first of the grass to the fattening in preference to the rearing, stock. This practice tends to increase the quantity of grass, which has thus time to get up, and the ground being fresh and unsaturated, when the stock returns to it, more especially if rain has fallen, they will feed with greater appetite and relish. The dung dropped by the stock, while feeding, should be spread about, instead of being suffered to remain where it was deposited, in a solid body. Where the larger and the smaller kinds of stock are to be fed on the same pastures, the larger species should have the first bite, and it is not thought by some advisable to depasture land with a mixed collection of different species of live stock unless the field is extensive, or unless the herbage varies in different parts of the field. It is generally found, that the grass produced by the dung of cattle or horses is injurious to sheep, producing grass of too rich a quality for that species of stock. There is no mode by which such pastures are more effectually improved than by the application of lime, either spread upon the surface or mixed with the soil. In the latter case, it is essential that the lime should be mixed with the surface soil only as lime is apt to sink, if covered deeply by the plough. The coarse grasses would, in that case, regain possession of the soil, and the dung afterwards deposited by the cattle will not enrich the land in the same manner as if the lime had been incorporated with the surface only. (*Code.*)

5842. *Mountainous pastures*, from which the plough is altogether excluded, have been commonly classed among waste lands even such of them as bear herbage by no means of inconsiderable value as well as heaths and moors with patches of which the green pastures are often chequered. The general term wastes is therefore a very indefinite expression, and, indeed, is not unfrequently made to comprehend all that extensive division of our territory that neither produces corn nor rich herbage. Yet it is on such tracts that by far the greater part of our butcher's meat and wool is grown, and not a little of the farmer fully prepared for the market. Foreigners and superficial readers at home must accordingly be greatly mistaken, if they imagine that what are called wastes by the Board of Agriculture, and other writers on rural economy, are really altogether unproductive, and it would be a still grosser error to believe that all those wastes owe their continuance to neglect or mismanagement, and that any exertions of human industry can ever render the greater part of them, including all the mountainous tract of Great Britain, more valuable than they are at present, without a much greater

expenditure of capital than, under almost any circumstances, they could possibly return. (*Sup. art. Agr.*)

5843. *Monteth of Closeburn*, in Dumfriesshire, has regenerated old pasture by paring up the turf with a paring plough or spade, laying it to one side for a week or two, and again replacing it where it was before, after the subsoil had been stirred by ploughing and harrowing, and a little lime, ashes, or other manure added. A field so treated was found, in four years, to keep fifteen head of cattle fully better than it did ten in its former state. The improvement is considered to give of annual profit one third of the prime cost, so that in little more than four years it will clear itself. (*Gard. Mag.* vol vi.)

5844. *Improving pasture without taking a crop of corn.* The same gentleman having had a considerable extent of the poorest moorland in Scotland in his estate of Closeburn, Dumfriesshire, entertained the opinion that it might pay six improving the pasture without taking a crop of corn from this poor soil, which in general was a peat earth upon a gravel or sand or red freestone, and which he considered too poor to produce a remunerating crop of corn. He accordingly set to work to improve about a thousand acres of this poor soil from four hundred to eight hundred feet above the sea, and sometimes pared and burned nearly two hundred acres in one summer which he ploughed in the autumn and allowed to lie in that state till the next spring when he laid on about one hundred and seventy bushels of quicklime or lime shells, as they are there called from their shelling or falling to pieces when watered per English acre, and in the month of July harrowed in between five and six bushels of *H. lanatus* grass seed. The greatest part of this land has now been improved about twenty years, and is continuing to yield abundance of grass and is worth from £2s. to 14s. per acre, while in its natural state it was scarcely worth 2s. and Mr M. is convinced it would pay amply for another dressing of lime, which a Scottish farmer he says, would not think of, as the plough is upon all occasions the implement in most active operation with him. In the improvement of moor ground, Mr M. thinks it highly important to state that the very worst effects result from pulverising or bringing the peaty or vegetable soil to a complete state of putrefaction or pulverisation, before being laid down to pasture and that this must certainly take place when two or three corn crops are taken before sowing out. Moory peaty soil after this treatment is liable to be poached in wet weather and in dry weather is almost equally incoherent, and is difficult to be again restored without dung or great quantities of earth. (*C. G. Stuart Monteth's* March 1830, in *Gard. Mag.* vol vi.)

5845. *The chief improvements of which mountainous pastures are susceptible* are draining and sheltering by plantations. Some parts might probably be enclosed by stripes of plantation between stone walls, or by stone walls alone but as the stock on mountain pastures are generally under the care of a herdsman the advantages of change of pasture and alternate eating down and saving or sparing the grass, by keeping out the cattle, are obtainable without the use of fields.

### SECT. III. Improvement of Grass Lands, by a temporary Conversion to Tillage

5846. *The practice of breaking up grass lands*, either with a view to their being soon after restored or to their permanent retention in aration has occasioned much discussion and even attracted the attention of the Legislature, and the Board of Agriculture. In *The Code of Agriculture* it is stated that a much larger proportion of the united kingdom, than is at present so cultivated, might be subjected to the alternate system of husbandry or transferred from grass to tillage, and then restored to grass. Much of the middling sorts of grass lands, from 200 to 400 feet above the level of the sea, is of this description and many husbandmen and most indiscriminate friends of the corn laws and the landed monopoly regret that such lands are left in a state of unproductive pasturage, and excluded from tillage. Were the trade in corn free, the idea of tilling such lands would be at least problematical.

5847. *A very extensive enquiry* was made in consequence of a requisition from the House of Lords to the Board of Agriculture, in December 1808 "into the best means of converting certain portions of grass lands into tillage, without exhausting the soil and of returning the same to grass, after a certain period, in an improved state, or at least without injury and the information collected by the Board upon that subject, is in the highest degree satisfactory and important.

5848. *On this subject the opinion of one of our first writers* is, "that though it is impossible to deny that much grass land in England would be more productive, both to the proprietor and occupier under a good course of cropping than under pasture; yet it is no less certain that there are large tracts of rich grazing land which, in the present state of the demand for the produce of grass lands, and of the law of England with regard to tithes, cannot be employed more profitably for the parties concerned, than in pasture. The interest which the Board of Agriculture has taken in this question with a view to an abundant supply of corn for the wants of a rapidly increasing population seems, therefore, not to have been well directed. Instead of devoting a large portion of their volumes to the instruction of farmers regarding the best method of bringing grass lands into tillage and restoring them again to meadow or pasture, without deterioration the first thing required was to attempt removing the almost insuperable obstruction of tithes, by proposing to the legislature an equitable plan of commutation. If some beneficial arrangement were adopted on this head, there is no reason to doubt, that individual interest would soon operate the wished-for change, and that all grass lands capable of yielding more real and profit under tillage than under pasture would be subjected to the plough as fast as the demands of the population might require. (*Sup. B. art. Agr.*)

5849. *In giving the essence of the information collected by the Board*, we shall first state the opinions as to such grass lands as should not be broken up, and next the directions for breaking up and laying down the others.

#### SUBSECT. 1. Grass Lands that ought not to be broken up by the Plough.

5850. *There are various sorts of grass lands that ought not to be broken up*; as water meadows; salt marshes lands apt to be overflowed; lands near large populous towns, where the produce of grass land is always in demand, and consequently dear; and low-lying tracts, in the valleys of mountainous countries, particularly in chalky districts, where old meadow land is scarce, and where a portion of it, to raise early and late food for stock gives a great additional value to the adjoining upland. But whether rich lands which have long remained in grass, and continue productive, should ever be converted into tillage, is a question respecting which a great diversity of opinion has been entertained.

5851 *The lands considered as best adapted for permanent pasture* are of three kinds strong tenacious clays, unfit for turnips or barley which are said to improve the more the longer they are kept under a judicious system in grass soft clayey loams, with a clayey or marly bottom or substratum, and rich, sound, deep-soiled land, or vale land, enriched by nature at the expense of the higher grounds, generally lying in a situation favourable with respect to climate.

5852. *The advantages of such pastures* are represented in the strongest light. It is affirmed, that they feed cattle to a greater weight, that they are not so easily scorched by the summer's drought; that the grasses are more nutritive, both for sheep and cattle that much corn fed upon them give richer milk, and more butter and cheese; that the horns of all animals pastured on them are much better preserved; that they produce a greater variety of grasses, that, when properly laid down, they yield a succession of pasture throughout the whole season, that the herbage is sweeter and more easily digested and that they return an immense produce at a trifling expense.

5853. *To break up lands possessing these advantages*, it is said, can only be justified by the most urgent public necessity and to prevent the horrors of famine. The real value of such lands will appear by considering their rent and produce. The grass lands in Lincolnshire are accounted the richest in the kingdom. The rents are various, from 1*l.* 1*s.* to 3*l.* per acre; and the value of the produce from 3*l.* per acre to 10*l.* This produce arises from beef, mutton, and wool, and is obtained subject to little variation from the nature of the seasons, and at a trifling expense. The stock maintained per acre on the best grassy lands surpasses what could be fed by any stable produce. It is not at all uncommon to feed at the rate of from six to seven sheep in summer and about two sheep in winter. The sheep, when put on the grass, may weigh from 16 lbs. to 50 lbs. per quarter and the increase of weight would be at the rate of 4 lbs. per quarter, or 16 lbs. per sheep. But suppose in all only 100 lbs. at 8*d.* per pound, that would amount to 3*l.* 1*7s.* 10*d.* The wool would be worth about two guineas more, besides the value of the winter keep and the total may be stated at about 7*l.* per acre, got at little expense. Such lands, it is evident, cannot be better employed than in feeding stock.

5854. *Grass land on tenacious clays and heavy loams*, when brought in a succession of years, or perhaps of ages, into a state of great productiveness, cannot be ploughed without the risk of great injury and are more profitable in the production of herbage than they could be in the production of grain.

5855 *Grass on deep-soiled sound vale lands* would be productive of corn if ploughed; but would be probably injured by cultivation from their texture being altered, and rendered unduly loose and open by tillage from the native plants being more or less destroyed or enfeebled; and from the great decomposition and waste of the principles of fertility resident in the soil.

5856. *The extent of these descriptions of land*, however is not so great that the advantages of breaking them up could probably ever be a national object, or worth the risk of injuring their future productiveness in grass. But there are pasture lands of an inferior sort, which are too apt to be confounded with those already described and respecting the propriety of occasionally appropriating them to arable culture, there can hardly be a doubt. Such lands do not depend upon their intrinsic fertility but upon annual supplies of manure derived from the arable land in their neighbourhood.

## SUBSECT. 2. *Advantages and Disadvantages of breaking up Grass Lands.*

5857 *The advantages of breaking up grass lands*, not of the richest quality will appear by a comparison of their produce with that of arable lands.

5858. *From the enquiry of the Board of Agriculture* it appears that an acre of clover, turnips, potatoes, turnips, cole, or cabbages, will furnish at least three as much food as the same acre would have done, had it remained in pasture of a medium quality; and, consequently that the same extent of land would maintain at least as much stock as when in grass besides producing every other year a valuable crop of corn; and this, independently of the value of the straw which whether consumed as litter or as food for cattle, will add considerably to the stock of manure. It follows that, with the exception of rich pastures, arable land is, on an average, superior to grass land, with respect to furnishing articles of human food, in the proportion of three to one, and consequently every piece of land unnecessarily kept in grass, the produce of which will only maintain one person, is depriving the community of food capable of maintaining two additional members.

5859. *The principal objection to the conversion of old turf into arable land* arises from an alleged inferiority both in bulk and nutritive properties, in the new when compared to the old herbage. It is certain, that by no art can we at once produce a surface of grasses which can be at all compared to some of the richest pastures in Buckinghamshire, Lincolnshire, and Leicestershire; but there are not the pastures which any prudent agriculturist would recommend to be broken up, whatever might be the price of corn; and more especially in Britain, and with a prospect of the trade in corn being at no distant period open. Still in by far the greater number of cases where the soil will admit of the convertible husbandry and where that husbandry is as well understood and practised as it is in the north of England and south of Scotland, we should have no hesitation in leaving it to the farmer to break up whatever pastures he thought he could do with profit during a fourteen or twenty one years lease. A gentleman who had a large farm, principally consisting of strong rich clay (every field of which with hardly any exception, he occasionally broke up) was accustomed to lay them down with a crop of barley and to sow fourteen pounds of white clover a peck of rib-grass, and three quarters of hay seeds, per acre. By this liberal allowance of seed, he always secured a thick coat of herbage the first year which differed from old pasture in being more brilliant. Some lands, therefore, under judicious management, will rarely be injured by the plough. When laid down from diluvial soils they may not carry for the first year or two such heavy cattle as they would afterwards; but they will support more in number, though of a smaller size, and bring a greater weight of butcher meat to market. It is often desirable to keep one or two moderate-sized enclosures, of from ten to twenty acres, according to the size of the farm, in permanent pasture, for the feeding of cattle and sheep, and as a resource for the stock to go to in case of a severe spring or summer drought. But the relinquish of any considerable portion of a farm in old turf or permanent pasture, unless of the richest quality, is in general injurious to the landlord, the tenant, and the public. The value of any estate, where the system of permanent pasture has been carried to an unreasonable extent, may be easily and greatly augmented by appropriating the manure of the farm to turnips and other great crops, and by the adoption of the convertible system of husbandry.

8860. *There are many cases where this doctrine, though in general to be recommended, ought not to be carried to its full extent.* In Scotland, where the land is commonly light, and where the sheep are both bred and fed upon the same farms, a proportion of permanent pasture is essential. Much injury in particular has been sustained by breaking up permanent pastures on such soils, more especially where subject to rotational tithes. Many lands of an inferior soil, which kept two sheep on an acre, paying only virtual tithes, and rented at ten shillings per acre, since they have been broken up cannot pay, even without rent, the tithe of corn and the expense of cultivation. A farm in general lets best with a fair proportion of grass land upon it, which admits of a mixed management; in consequence of which, if one object fails another may be successful.

8861. *With respect to the disadvantages of breaking up pastures* it is alleged in *The Code of Agriculture*, that there is a risk of tenants breaking through their engagements (p. 473. 3d edit.) by which we suppose is to be understood, the chance of their taking a few good crops from the newly broke-up lands and then leaving the farm. Tenants who would do this must certainly be as wicked as the landlords who would put in their power would be imbecile. No other disadvantage is stated, and thus may safely be left to their own cure.

### Summary. 3. Breaking up Grass Lands, and afterwards restoring them to Grass.

8862. *On the subject of breaking up and laying down grass lands*, the following particulars are discussed in the *Code of Agriculture* as the result of the information communicated to the Board. — Whether any previous steps are necessary before lands in grass are broken up? the proper mode of effecting that object the course of crops the manure necessary the system of management during the rotation the mode of laying down the land again to grass that of sowing the grass-seeds and the subsequent management.

8863. *If the land be wet*, it is advisable to drain it completely, previously to its being broken up, for it is not improbable that its being kept in pasture was partly on account of its wetness.

8864. *Land that has been long in pasture* does not require dung during the first course of crops that is taken after being broken up but the application of calcareous manure is always, in such cases, expedient. Sometimes lime is spread on the ground before it is ploughed, at other times when it is either under summer fallow or a drilth crop of turneps. Marl and chalk also have been used for the same purpose with great advantage. The law therefore derives additional strength and vigour, the succeeding crops are much improved; the soil is commonly so softened in its texture that it may be ploughed with half the strength that would otherwise be necessary and whenever it is restored to grass, the herbage is abundant.

8865. *Wherever the soil is not too shallow*, nor of a friable nature or when the turf cannot soon be rotted, if land is to be broken up from old pasture the system of paring and burning is proper. In this way good tilth is speedily procured the damage that might otherwise be sustained by the grub, the wire-worm, and other insects, is avoided, while the soil receives a stimulus which ensures an abundant crop.

8866. *Where paring and burning cannot take place*, the land may be trenched or double-ploughed. This is effected by means of two ploughs following each other the first plough taking off a thin surface of about three inches, and the second going deeper in the same place, covering the surface-soil with fine mould, both furrows not exceeding the thickness of the vegetable mould or other good soil. If the land is ploughed with one furrow the operation ought to be performed before winter that it may receive the benefit of the success up frosts, by which the success of the future operations will not only be promoted but most of the weeds lodged in the soil will be destroyed. When one furrow alone is taken the best size is 8 or 10 inches and a half deep by eight or nine broad. The strain on horses in ploughing lay land is mostly from the depth.

8867. *The rotation of crops to be adopted*, when grass lands are broken up, must partly depend upon the soil and partly on the manner in which it is prepared for cultivation. As a general principle, however, it may be laid down, that unless by the course of cropping to be pursued the bad grasses and other plants indigenous to the soil are extirpated, they will, when the land is again laid down to grass, increase and prevail with more rapidity and effect than seeds chosen by the farmer and the consequence must be, a heavy disappointment in the future crops of grass, perhaps solely or at least principally attributable to a previous defective management. It is necessary therefore, to enter into details upon this subject as applicable to clay chalk, peat, loam, and sand.

8868. *Clay*. The process of conversion in clayey soils should be commenced with paring and burning, especially where the grub is suspected. The following course may then be adopted — 1. Rays, fed with sheep; 2. beans 3. wheat, 4. beans; 5. wheat, 6. fallow; 7. wheat, sown with grass-seeds. This may seem severe cropping but it is justified by experience when old grass clay land is broken up. If the land has not been pared and burnt, the first crop ought to be either oats or dibbled beans. To do justice to the plan of restoring the land to grass, there ought to be, in all cases according to the soil, either a sowed or turnip fallow before the sowing of grass-seeds is attempted. But on mellow heavy clay land consisting of this old grass pasture, where it is thought necessary or advisable to break up such land, it should be done in detached pieces, so as to suit the convenience of the occupier and the following course should be adopted — 1. Autumnal ploughing for oats in spring 2. fallow for rape to be sown with sheep 3. beans 4. wheat, sown with clover, 5. clover 6. clover 7. wheat 8. rape, to be partially eaten, and hoed in spring, and to stand for seed; and 9. wheat with grass-seeds. This is a very profitable rotation, and applicable to the best grassy land in Lincolnshire.

8869. *Chalk*. Paring and burning are considered in this case to be indispensable as a preparation for turnips, which ought, where manure can be got, to be raised two years in succession, then barley clover wheat; and, after one or two additional crops of turnips the land may be laid down with sainfoin to great advantage.

8870. *Peat*. On this soil paring and burning are essentially necessary. Under a judicious system, the greatest and quickest profit is thus secured to the farmer with advantage to the public, and without injury to the landlord. Draining also must not be neglected. The crops to be grown on peat soils are, 1. rape or potatoes 2. oats 3. turnips 4. oats or wheat and 5. clover or grass seeds. A liberal application

of lime, where it can be obtained, is of the greatest service in enabling such soils to bring corn to its full perfection. In the *Annals of Thory* the following course was recommended:—1 Fallow and burning for rape; 2 oats; and 3 wheat with grass-seeds; if the land were safe from water the Lammus sort, if not, spring wheat. This short course, it is contended, preserves the land in heart; and it afterwards produces abundant crops of grain. But long courses, in such a soil, run the lands to weeds and straw without quality in the grain.

5872. *Laws.* The courses of crops applicable to this soil are too numerous to be here inserted. If the sward is friable, the following rotation may be adopted—1 Oats 2 turnips, 3 wheat or barley, 4 beans; 5 wheat; 6 fallow or turnips 7 wheat or barley, and grass-seeds. If the sward is very tough and coarse, instead of taking oats, it may be pared and burnt for turnips.

5873. *Seed.* On rich and deep sandy soils, the most valuable that can be raised is a crop of carrots. For inferior sands, turnips, to be eaten on the ground which should then be laid down with barley and grass-seeds.

5873. According to the improved system of laying down lands to grass, land ought to be previously made as clean and fertile as possible. With that view all the green crops raised ought to be consumed upon the ground fallow or fallow crops ought not to be neglected; and the whole straw of the corn crops should be converted into manure, and applied to the soil that produced it. Above all, the mixing of calcareous matter with the soil, either previously to, or during the course of, cropping, is essential. Nothing generally improves meadows or pastures more than lime or marl they sweeten the herbage, render it more palatable to stock, and give it more nourishing properties.

5874. When turnips are raised upon light land, sheep should be folded on them whereas, if the land is strong or wet, the crop should be drawn, and fed in some adjoining grass-field or in sheds. If the land is in high condition, it is customary to eat off half the turnips, and eat the other on the ground. But this is not a plan to be recommended on poor soils.

5875. It has been disputed whether grass-seeds should be sown with or without corn. In favour of the first practice, that of uniting the two crops, it is maintained, that where equal pains are taken the future crop of grass will succeed as well as if they had been sown separately while the same fifth answers for both. On the other hand, it is observed, that as the land must, in that case, be put into the best possible order there is a risk that the corn-crop will grow so luxuriantly as to overpower the grass-seeds, and, at any rate, will exclude them from the benefit of the air and the dew. If the season also be wet, a corn crop is apt to lodge, and the grass will, in a great measure, be destroyed. On soils moderately fertile, the grasses have a better chance of succeeding but then, it is said, that the land is so much exhausted by producing the corn-crops, that it seldom proves good grass land afterwards. In answer to these objections it has been urged, that where, from the richness of the soil, there is any risk of sowing a full crop of corn, less seed is used, even as low as one third of the usual quantity, and that a moderate crop of grain nurtures the young plants of grass, and protects them from the rays of a hot sun, without producing any material injury. Where the two crops are united, barley is the preferable grain except on peat. Barley has a tendency to loosen the texture of the ground in which it grows, which is favourable to the vegetation of grass-seeds. In the choice of barley, that sort should be preferred which runs least to straw and which is the soonest ripe. On peat, a crop of oats is to be preferred. The most recent produce of the best farmers is in favour of sowing the grass-seeds without the addition of corn, or any other temporary plant.

5876. The manner of sowing the grass-seeds also requires to be particularly attended to. Machines have been invented for that purpose, which answer well, but they are unfortunately too expensive for the generality of farmers. It is a bad system, to mix seeds of different plants before sowing them, in order to have the fewer casts. It is better to sow each sort separately for the expense of going several times over the ground is nothing, compared to the benefit of having each sort equally distributed. The seeds of grasses being so light, ought never to be sown in a windy day except by machinery an equal delivery being a point of great consequence. Wet weather ought likewise to be avoided, as the least degree of peaching is injurious. Grass seeds ought to be well harrowed, according to the nature of the soil.

5877. When the corn is carried off, the young crop of grass should be but little fed during autumn, and that only in dry weather but heavily rolled in the following spring, in order to press the seed home to the roots. It is then to be trusted as permanent pasture. By attention to these particulars, the far greater proportion of the meadows and pastures in the kingdom, of an inferior or even medium quality may be broken up, not only with safety but with great profit to all concerned.

## CHAP. VIII.

### *Plants cultivated on a limited Scale for various Arts and Manufactures.*

5878. The plants used as food for men and animals are by far the most generally cultivated in every country and, next, those of clothing, building and other arts of convenience or luxury. The former are often called agricultural, and the latter commercial or manufactorial plants. Of manufactorial plants, only a few are at present cultivated in Britain the national policy rendering it preferable to import them, or substitutes, from other countries. Some, however are still grown in nearly sufficient quantities for home consumption, as the hop, mustard, rape, and a considerable quantity of flax, anise, and carraway, some hemp, teasle, and woad are also raised. These and other plants may be classed as grown for the clothing, distilling, brewing, oil-making, and domestic and medical arts.

#### SECT. I. *Plants grown chiefly for the Clothing Arts.*

5879. The clothing plants are flax, hemp, teasle, madder, woad, and weld; the first three are used by the manufacturer of the fabric, and the others by the dyer.

**SUMMARY 1** *Flax* — *Linum catharticum* L. *Pentstemon Pentagynus* L. and *Linum*  
Dec. *Lin.* Fr *Flacks*, Ger and *Lino*, Ital. and Span. (fig 797 a)

5880. The flax has been cultivated

from the earliest ages, and for an unknown length of time in Britain, of which it is now considered a naturalised inhabitant. It is cultivated both for its fibre for making thread, and its seed for being crushed for oil but never has been grown in sufficient quantity for either purpose. The legislature of the country as Brown observes, has paid more attention to framing laws regarding the husbandry of flax than to any other branch of rural economy but it need not excite surprise that these laws, even though accompanied by premiums have failed to induce men to act in a manner contrary to their own interest. The fact is, the culture of flax is found on the whole less profitable than the culture of corn. It is one of the most severe crops when allowed to ripen its seed but by no means so when pulled green.

5881 The varieties of the common flax are few and scarcely deserving of notice. Marshall mentions the blue or lead-coloured flax as being

cultivated in Yorkshire and Professor Thaeer mentions a finer and coarser variety he also as well as some other agriculturists has tried the *Linum perenne* (b) but though it affords a strong fibre, it is coarse and difficult to separate from the woody matter.

5882 The soils most proper for flax besides the alluvial kinds, are deep and friable loams, and such as contain a large proportion of vegetable matter in their composition. Strong clays do not answer well, nor soils of a gravelly or dry sandy nature. But whatever is the kind of soil it ought neither to be in too poor nor in too rich a condition because in the latter case, the flax is apt to grow too luxuriantly and to produce a coarse sort and in the former case the plant, from growing weakly, affords only a small produce (Tr. on Rural Affairs)

5883 If there is water at a small depth below the surface of the ground, it is thought by some still better as in Zealand which is remarkable for the fineness of its flax and where the soil is deep and rather stiff with water almost every where at the depth of a foot and a half or two feet. It is said to be owing to the want of this advantage that the other provinces of Holland do not succeed equally well in the culture of this useful plant not but that fine flax is also raised on high lands if they have been well tilled and manured and if the seasons are not very dry. It is remarked in the letters of the Dublin Agricultural Society that moist stiff soils yield much larger quantities of flax, and far better seed than can be obtained from light lands and that the seed secured from the former may with proper care be rendered full as good as any that is imported from Flax or Zealand. M. Du Hamel, however thinks that strong land can hardly yield such fine flax as lighter ground.

5884 The place of flax in a rotation of crops is various, but in general it is considered as a corn or exhausting crop when the seed is allowed to ripen and as a green or pea, or bean crop, when the plant is pulled green.

5885 Flax Donaldson observes, is sown after all sorts of crops, but is found to succeed best on lands lately broken up from grass. In Scotland, the most skilful cultivators of flax generally prefer lands from which one crop of grain only has been taken, after having been several years in pasture. When such lands have been limed or manured immediately before being laid down to grass, the crop of flax seldom or never misgives, unless the season prove remarkably adverse. In the north of Ireland flax is generally sown by the small farmers after potatoes. In Belgium it is supposed not to do well after peas or beans nor to succeed if sown oftener on the same soil than twice in nine years. (Tr. on Thaeer)

5886 The preparation of the soil, when grass land is intended for flax consists in breaking it up as early in the season as possible so that the soil may be duly mellowed by the winter frosts, and in good order for being reduced by the harrows, when the seed process is attempted. If flax is to succeed a corn crop, the like care is required to procure the aid of frost, without which the surface cannot be rendered fine enough for receiving the seed. Less frost, however will do in the latter than in the former case, therefore the grass land ought always to be earliest ploughed. At seed-time, harrow the land well before the seed is distributed then cover the seed to a sufficient depth by giving a close double harrowing with the harrows. Water furrow the land and remove any stones and roots that may remain on the surface which finishes the seed process.

5887 The ordinary season of sowing flax seed is from the middle of March to the middle or end of April, but the last week of March and the first ten days of April are esteemed the best time and accordingly within these periods the greatest quantity of flax seed is sown in this country. In France and Italy it is often sown in the autumn by which a larger crop is produced, especially when seed is desired.

5888 The quantity of seed depends on the intention of the crop. When a crop of seed is intended to be taken, thin sowing is preferable, in order that the plants may have room to throw out lateral shoots, and to obtain air in the blossoming and filling seasons.

But it is a mistake to sow thin when flax is intended to be taken; for the crop then becomes coarse, and often unproductive. From eight to ten pecks per acre is the proper quantity in the last case, but when seed is the object, six pecks will do very well. (*Brown.*) Thick-sown flax runs up in height, and produces fine soft flax if sown thin, it does not rise so high, but spreads more and puts forth many side branches, which produce abundance of seed, and such seed is much better filled, plumper and heavier than the seed produced from thick-sown flax (*Donaldson.*)

5889. *In the choice of seed, that which is of a bright brownish colour, only to the feel and at the same time weighty, is considered the best.*

5890. *Linseed, imported from various countries, is employed. That brought from Holland is, however in the highest estimation; as it not only ripens sooner than any other that is imported, but also produces greater crops, and flax of that quality which best suits the chief manufactures of the country. American seed produces, in common, fine flax but neither the quantity of flax nor of the pods, provincially the "bolls," which contain the seeds, is so large as the produce from Dutch linseed. Flax seed yields a very scarce sort of flax, but a greater quantity of seeds than any other. It is common in some parts of Scotland to sow seeds saved from the crop of the preceding year especially when that crop was raised from seed imported from Holland. The success of this practice is found to depend greatly on changing the seed from one sort of soil to another of an opposite nature but the saving in the expense of purchasing that sort of seed, in place of what is newly imported from Holland is so inconsiderable, and the risk of the crop misgiving so much greater in the one case than in the other that those only who are ignorant of the consequences, or who are compelled from necessity are chargeable with this act of ill-judged parsimony. Flax seed is by some farmers changed every three years, but many have sown the same seed two years in succession without perceiving any degeneracy. When any degeneracy takes place, the seed of flax grown on a different soil, as moor, moor sand, &c. without any view to the produce in fibre will, it is said, answer as well as foreign seed.*

5891. *The manner of sowing is almost always the same but when seed is the main object, drilling may be adopted by which seed will be saved in sowing cleaning conducted at less expense, and the plants rendered more vigorous and branchy by the stirring of the soil and the admission of air between the rows. The fibres of flax grown in this way however will be shorter and less equal in thickness throughout their length than flax grown by the broad-cast mode and tolerably thick.*

5892. *The after-culture of flax consists chiefly in weeding but sometimes it commences with rolling the surface, which is a very proper operation when the soil is very dry the season advanced, or the earth very porous. By this process the earth is pressed firmly to the seeds, and they are thereby stimulated to vegetate sooner, and the drought is kept out. On some soils, and in wet or stormy seasons, flax is apt to be laid to guard against which some cultivators run across their flax field slender poles fixed to stakes but a better method is to run small ropes across the field, both lengthwise and breadthwise, where necessary for these being fastened where they intersect one another and supported by stakes at due distances, form a kind of network which is proof against almost every accident that can happen from tempestuous weather.*

5893. *In Scotland a crop of flax, it is said, has been sometimes weeded by turning a flock of sheep at large into the field. They will not taste the young flax plants, but they carefully search for the weeds, which they devour.*

5894. *The flax crop is taken by pulling on which there is a considerable difference of opinion. Some, however think of pulling it before it comes into flower when fibre is the sole object or before the seed in the capsules acquires a brownish colour, when fibre and seed jointly are required or when seed alone is the object.*

5895. *Some argue for it pulling while green, in order that its fibres may be softer and finer, others, with the same view pull it up before its seeds are quite formed and others again think that it should not be pulled till some of the capsules which contain the seeds have begun to open being of opinion that the fibres of green flax are too tender and that they fall too tow. On the other hand it is certain the fibres of flax which has stood till it is very ripe are always stiff and harsh that they are not easily separated from the seed, and that they do not bleach well. Here, therefore, as in most other cases, both extremes should be avoided and it consequently seems most reasonable to think that the properest time for pulling flax, is when its stalks begin to turn from a green to a yellow, when its leaves begin to fall and when its seeds begin to be brown. Donaldson observes, that a crop of flax frequently grows short, and runs out a great number of seed-bearing branches. When that is the case the seeds, not the flax ought to be the farmer's chief object, and the crop should be allowed to stand till the seeds are in a great measure perfected. But that when the crop thrives, and is likely to become more valuable for the flax than the seeds, it should be pulled soon after the bloom drops off, and before the pods turn hard and sharp in the points. When flax is grown for its fibre, Brown considers it the safest course to take it a little early any thing wanting in quantity being, in this way, made up by the superiority of quality.*

5896. *The operation of pulling flax differs according to the intention of the crop. When it is grown for the fibre it is pulled and tied into sheaves like corn, and carried off immediately to be watered. But when the seed is to be taken from the plant, it is pulled and laid in bundles.*

5897. *In pulling flax, it is usual, when it is intended to save the seeds to lay it by bundles, partly across each other; the reason for which is, that the business of ridding is thereby facilitated, as the rippers, in place of having to separate each bundle from the bundle, find it by this simple precaution already done to their hand. Although it is of much importance, yet it very seldom happens that much attention is bestowed in separating the different sorts of flax from each other, in pulling the crop. In most fields, there are varieties of sorts; of course some parts of a field will produce fine flax, of other sorts; some better, and some that; in a word, crops of different lengths and qualities. It cannot be supposed that all these sorts of flax will undergo an equal degree of rotting, grouting, bleaching, and bleaching, without sustaining great injury. To do this flax is pulled, it is laid together by handfuls, with the seed end turned to the south. These handfuls should*

*rather lie quite in a line with each other or directly across but, little heed being given, so that the air may easily pass through them. Some instead of this method lay the handfuls of flax loosely at the top, that spread out their roots, and thus set several of them together upright upon their roots. In either of these ways the flax is generally left two or three days in the field to dry it. The drying is scarcely not necessary for the drying, because the fibre will separate the capsules from the flax as effectually before it has been dried as it will afterwards; and if it is done with a view to ripen the seed, it should be considered that the flax will be more hurt by the longer time of sleeping, which will become necessary in consequence of this drying, than the seed can be benefited by because the more the moisture which remains in the flax so the seed is dried, the greater must be the degree of putrefaction necessary to loosen and destroy the cohesion of this cohesion but sometimes the flax or parts of the flax must occasionally be*

decreased by the degree of putrefaction, and if the putrefaction does not arise to such a degree as to destroy the cohesion of the mass, the fibres of the flax will adhere so strongly to the root that the force necessary in combing will prove

equally detrimental to the flax. The practice adopted in some parts of Brittany seems therefore much more sound, which is 1. rippling, 2. flax after it has lain 6 or 8 days in the sun, 3. flax after it has lain 6 or 8 days in the sun, 4. flax after it has lain 6 or 8 days in the sun, 5. flax after it has lain 6 or 8 days in the sun.

5899 In the process of rippling, which is the next operation, a large cloth should be spread on a convenient spot of ground, with the ripple placed in the middle of it.

5900 In performing this business the pods containing the seeds are forced from the stalks by means of the iron comb called a ripple fixed on a beam of wood, on the ends of which two persons sit, who, by pulling the seed end of the flax repeatedly through this comb, execute the operation in a very complete manner. It is remarked by the author of *The Present State of Husbandry in Great Britain*, that those who bestow much attention on the cultivation of flax in Scotland generally ripple off the seed, even when there is no intention of saving it. As it is found when flax is put into water without taking off the pods, the water soon becomes putrid, in consequence of which the flax is greatly injured.

5901 The management of the capsules, and the separation of the seed, form the next operation.

5902 The capsules obtained should be spread in the sun to dry, and those which separate from the pods of their own accord being the fullest and ripest, should be set apart for sowing, in case the precaution of raising some flax purposely for seed has not been attended to. The capsules are then broken, either by treading or by threshing, in order to get out the remaining seeds, the whole of which, as well as the others, should be carefully sifted, winnowed, and cleaned. When the seed is laid up, it must be frequently stirred, or trampled, to prevent its heating. Even the second seed affords a considerable profit, by the oil which it yields, and also by being used when broken for fattening of cattle.

5903. To facilitate the separation of the fibre from the bark it is necessary to accelerate the process of decay or putrefaction. This may be done in different ways, but the chief are bleaching alone, and steeping and bleaching.

5904 Bleaching is a tedious and laborious operation when it is intended as a substitute for steeping, but it is less likely to injure the fibre, and may be adopted on a small scale when steeping places are not at hand. In some countries, and in some other places, flax, instead of being steeped, is what is called dew retted; that is, the stalks are allowed to arrive at that state in which the hard or woody parts separate most easily from the boon seed or fibre by a more gradual process, that of ripening by the action and influence of the dew. This is nothing more than exposing the flax to the influence of the weather for a longer period than is necessary when the operation of watering has been previously performed. Steeping, however, is the most universal practice both in Britain and on the Continent.

5905 Steeping or soaking, however, is and will be the general practice till flax dressing machines come into universal use. In performing this operation the flax, whether it has been dried and rippled, or pulled green, is loosely laid into small bundles, the smaller the better, because it is then most equally watered, and these bundles are built in the pool in a reclining upright posture, so that the weight placed above may keep the whole firmly down. The weights made use of are commonly staves placed on plants, or directly on the flax.

5906 The French mode of steeping flax, as described by Ratchiff, is said to improve the quality of the flax, and greatly increase its whiteness. This mode differs from the common practice, in placing the bundles in the steep vertically instead of horizontally, in immersing the flax by means of transverse sticks, with that degree of weight annexed which shall not push it down to the bottom, but leave it the power to descend spontaneously towards the conclusion of the steepage, and in leaving at first a space of at least half a foot between the bottom and the flax, and the flax, the spontaneous descent of the flax is an indication of its being sufficiently steeped, and the strength and quality of the fibre are said to be much better preserved by this mode, in which the temperature of the atmosphere acts with most force on the upper part of the plant, which needs it most.

5907 The water most proper for steeping flax should be clear, soft, and in standing pools. Compared with running water, pools occasion the flax to have a better colour: to be sooner ready for the grass, and even to be of superior quality in every respect. When soft, clear stagnating water cannot be obtained without art, a pit or canal is commonly formed adjoining to a river or stream, whence water can be easily brought. This pit or canal is filled with water for some time (a week or two) before it is proposed to pull the flax, by this means the water acquires a greater degree of warmth than river water possesses, which contributes greatly to facilitate the object. Farmers have in view in immersing green flax in water, namely to make the hard or woody substance part easily and completely from the boon or seed.

5908 The period that flax ought to remain in the water depends on various circumstances, as the state of ripeness in which it was pulled, the quality and temperature of the water, &c. The most certain rule by which to judge when flax is sufficiently watered is when the boon becomes brittle, and the hard separates easily from it. In warm weather ten days of the watering process are sufficient, but it is proper to examine the pools regularly after the seventh day, lest the flax should putrefy or rot, which sometimes happens in very warm weather. Twelve days will answer in any sort of weather, though it may be remarked that it is better to give too little of the water than too much, as any deficiency may be easily made up by suffering it to lie longer on the grass, whereas an excess of water admits of no remedy (Brown).

5909 Grassing or bleaching flax is the next operation, the intention of which is to rectify any defect in the watering process, and carry on the putrefactive process to that point when the fibre will separate from the bark, boon seed, or hard (as the woody part of the stem is called) with the greatest ease. In performing this operation the flax is spread very thin on the ground and in regular rows, the one being made to overlap the other a few inches with a view of preventing, as much as possible, its being torn up and scattered by gales of wind. Old grass ground, where the herbage does not grow to any great height, is the best for the purpose, as when the flax is covered by the grass or weeds, it is frequently rotted, or at least greatly injured thereby.

5910 The time allowed for grassing is regulated by the state of the flax, and seldom exceeds ten or twelve days. During this time it is repeatedly examined, and when it is found that the boon has become very brittle, so that, on being broken and rubbed between the hands, it easily and freely parts from the hard, it is taken up, a dry day being chosen for the purpose, and, being bound in sheaves, is either sent directly to the mill, which is the usual practice in the northern districts, or broken and sent by a machine or implement for the purpose.

5911 Steeping flax in hot water and soft soap (and to be the invention of Lees, and for which he was granted by parliament a secret or unrolled patent) is said to separate the fibre from the woody matter better than steeping in water simply, and this in the short space of two or three hours, and either with green flax or such as has been dried and stacked for months or years. When flax is to be separated by this new mode the cultivator has only to pull it in handfuls, dry it, and it into sheaves or faggots, and put it up in stacks like corn, till wanted by the manufacturer.

5912 The drawing of flax consists of various operations such as scutching, tracking, &c.

or breaking, by which the woody part is broken and heckling or combing, by which the fibre is separated from the woody part, and sorted into lengths. These operations are often all performed by the cottager or small farmer who grows flax for the purpose of spinning the fibre in his own family. But there are also public flax mills, impelled by water or other powers, by which flax is scutched, and it is then heckled by professional hecklers.

5915. *A method of preparing flax in such a manner as to resemble cotton in whiteness and softness, as well as in coherence is given in The Swedish Transactions for the year 1747.* For this purpose a little sea-water is to be put in an iron pot or an untinned copper kettle and a mixture of equal parts of brack-ashes and quicklime stirred upon it. A small bundle of flax is to be opened and spread, pour the surface and covered with some of the mixture, and the stratification continued till the vessel is sufficiently filled. The whole is then to be boiled with sea water for ten hours, fresh quantities of water being occasionally supplied in proportion to the evaporation, that the matter may never become dry. The boiled flax is to be immediately washed in the sea by a little at a time in a basket, with a smooth stick at first, while hot, and when grown cold enough to be borne by the hands it must be well rubbed washed with soap, laid to bleach, and tumbled and watered every day. Repeatedness of the washing with soap expedite the bleaching after which the flax is to be beat, and again well washed when dry it is to be worked and carded in the same manner as common cotton, and pressed between two boards for forty eight hours. It is now fully prepared and fit for use. It loses in this process nearly half its weight, which however is abundantly compensated by the improvement made in its quality.

798

5916. *Lee's method of breaking flax and hemp, without drawing was invented in 1810, and was the first step towards a great improvement, brought nearer perfection by the new patent machine of Messrs. Hill and Bundy.*

5917. *Hill and Bundy's machines (fig. 789) are portable, and may be worked on the side of an out-house. They are also well calculated for parishes, schools, and other charitable institutions, a great part of the work being so light that it may be done by children and women, or by such of the construction and simplicity of the machine, that no special instruction is required. It required the introduction of three rollers to those formerly used, the effect being a considerable reduction of the power. The woody part is removed in a very simple manner, the flax passing through a machine equally simple. The flax may be brought to any degree of fineness equal to the best used in France and the North of England for the finest lace and cambric. The original length of the fibre will be preserved.*

strength remains unimpaired and the difference of the produce is in nature being nearly two thirds one ton of flax being produced from four tons of seed. The expense of working each ton obtained by this method is only five pounds. The glutinous matter may be removed by soap and water only, which will bring the flax to such perfect whiteness, that no further bleaching is necessary even after the linen is woven and the whole process of preparing flax may be completed in six days.

5918. *The produce of flax in seed is generally from six to eight, sometimes as high as ten or twelve bushels per acre and the price depends in a great measure on that of foreign seed imported; as, when sold to oil-makers, it is generally about one half of that of Dutch seed sold for the purpose of sowing.*

5919. *The price of home-cultivated linseed is considerably advanced of late in some of the southern and western counties of the kingdom in proportion to what it is in the northern owing to the circumstance of its being much used as food for fattening cattle. The average price of the linseed cultivated in the kingdom at large cannot, it is supposed, be rated higher than from three to four shillings the bushel. The seed is separated into three qualities, the best for sowing, the second best for crushing for oil, and the inferior for boiling or steaming for cattle.*

5920. *The produce of flax in fibre varies exceedingly. Before being sorted the gross product of fibre varies from three cwt. to half a ton per acre.*

5921. *The use of flax in the linen manufacture is well known. The seed is crushed for oil, which is that in common use by painters. The cake or husk, which remains after the expression of the oil, is sold for fattening cattle and in some places as a manure, and the inferior seed, not fit to crush, is boiled and made into flax-seed jelly which is esteemed excellent nutriment for stock.*

5922. *As the making of flax-seed jelly is an agricultural operation, we shall here describe it. The proportion of water to seed is about seven to one. The seed having been steeped in part of the water for eight and forty hours previously to the boiling, the remainder of the water is added cold and the whole boiled gently about two hours, being kept in motion during the operation to prevent its burning to the boiler. Thus the whole is reduced to a jelly like or rather a glairy orropy substance. After being cooled in tubs, it is given, with a mixture of barley-meal bran and oat chaff, a bullock being allowed about two quarts of the jelly per day or somewhat more than one quart of seed in four days that is, about one sixteenth of the medium allowance of oil-cake.*

5923. *The diseases of flax are few and are chiefly the fly which sometimes attacks the plants when young, the mildew and the rust.*

SUBJECT 2 *Hemp*. — *Cannabis sativa* L. *Durcia Pentandra* L. and *Urtica* J. *Chanvre*, Fr. *Hanf*, Ger. *Canapa*, Ital. and *Canome*, Span.

5922. *The hemp* is a plant of equal antiquity with the flax. It is supposed to be a native of India, or of some other Asiatic country being too tender to be even naturalised in Europe. It is one of the few plants employed in British agriculture in which the male and female flowers are in different plants, a circumstance which has some influence on its culture and management. It grows to a great height on good soils sometimes to six or seven feet in this country but in Italy generally higher and Crud states, that in the Bolognese territory he has seen it fifteen feet eight inches high, and a friend of his eighteen feet six inches in both cases the fibre being of remarkable beauty. This luxuriance of the hemp in warm countries may be one reason why it has never been much cultivated in England. In the Isle of Axholme in Lincolnshire, it has been cultivated from time immemorial and also for some centuries in Suffolk, but chiefly for local manufacture. The culture, management, and uses of hemp are nearly the same as those of flax. When grown for seed, it is a very exhausting crop but when pulled green, it is considered a cleaner of the ground, and is said to have the property of preserving from insects any crop which it may surround. The objections to this crop are, that its coming in the midst of harvest is embarrassing, and that the attention it demands in every state of its progress is too great, where it is only a secondary consideration.

5923. *The soils* most suitable for hemp are those of the deep black putrid vegetable kind which have a situation low and somewhat inclined to moisture, as well as the deep mellow loamy or sandy sorts. But the quantity of produce is in general much greater on the former than the latter though, according to some, of an inferior quality. Mellow rich clayey loams do well and nothing better than old meadow land.

5924. *The preparation of the soil*, and the place in the rotation, are the same as for flax.

5925. *The season of sowing* is towards the end of April when there is no longer any danger of frost injuring the young plants. The quantity of seed is from two to three bushels according to the quality of the land. In quality the seed must be fresh heavy and bright in colour. Broad-cast is the universal mode of sowing and the only after-culture consists in keeping off bird when it is coming up in weeding and sometimes in supporting the crop by cross rods or lines as in the case of flax.

5926. *In taking the hemp crop*, two methods are in use according to the object in view. When the crop is grown entirely for the fibre it is pulled when in flower and no distinction made between the male and female plants. But as it is most commonly grown both with a view to fibre and seed the usual practice is to pull the male plants as soon as the setting of the seed in the females shows that they have effected their purpose. As the female plants require four or five weeks to ripen their seeds, the males are thus pulled so long before them.

5927. *In the operation of pulling the males* the pullers walk in the furrows between the ridges, and reach across to the crown of the ridge pulling one or two stalks at a time, and carefully avoiding to tread down the female plants. The male stalks are easily known by their yellowish hue and faded flowers.

They are tied in small bundles and immediately carried to the watering pool, in the manner of § 5. 528. *The operation of pulling the females* commences when the seed is ripe, which is known by the protrusion of greyish hue of the capsules and the fading of the leaves. The stalks are then pulled and laid up into bundles being set up in the same manner as grain until the seed becomes so dry and firm as to shed freely; great care should be taken in pulling not to shake the stalks rashly otherwise much of the seed may be lost. It is advised that after pulling the seed hemp may be set to stand in shocks if it is so late as to dry the seed but in order to prevent any delay in watering the seed pod may be cut off with a chopping knife, as I dried on canvas exposed to the air under some shed or cover. The method of drying the seed will prove of great advantage to the hump, as the seed and pods when green are of such a gummy nature that the stems might suffer much by sun-burning or rain, which will also colour and injure the hemp before the seed can be sufficiently dried upon the stalks. Besides the threshing out the seed would damage the hemp in a considerable degree.

5929. *Hemp is watered* (provin water retted) bleached (provin dew retted) and grazed in the same manner as flax. Grazing is omitted in some places, and drying substituted and in other districts watering is omitted with the female crop, which is dried and stacked and dewed or bleached the following spring. On the Continent hot water and green soap have been tried and here as in the case of flax it is found that steeping for two hours in this mixture is as effectual in separating the fibre from the woody matter as watering and grazing for weeks.

5930. *Although hemp in the process of manufacturing* passes through the hands of the breaker heckler spinner whitener weaver and bleacher yet many of these operations are frequently carried on by the same person. Some weavers bleach their own yarn and cloth, others their cloth only some heckle their tow, and put it out to spinning others buy the tow and put it out and some carry on the whole of the trade themselves.

5931. *The produce of hemp in fibre* varies from three to six cwt. per acre in seed from eleven to twelve bushels.

5932. *The uses of hemp* are well known, as well as its great importance to the navy for sails and cordage.

5933. *Exceedingly good buckram* is made from it, for towels and common table cloths. The low priced hempen cloths are a general wear for husbandmen servants, and labouring manufacturers; the better sorts for working in mers and tradesmen in the country and the finer ones, seven-eighths wide, are pre-

ferred by some gentlemen for strength and warmth. They possess this advantage over Irish and other hems, that their colour improves in wearing, while that of linen declines. English hemp, properly manufactured, stands unrivalled in its strength, and is superior in this respect to the Russian. Considerable quantities of cloth are imported from Russia for sheeting, merely on account of its strength, for it is warmer at the price than flannel. Our hempen cloth, however, is preferable, being stronger, from the superior quality of the thread, and at the same time lighter in wearing. The hemp raised in England is not of so dry and spongy a nature as what we have from Russia and India, and therefore it requires a smaller proportion of tar to manufacture it into cordage. Tar being cheaper than hemp, the rope-makers prefer foreign hemp to ours; because they can make a greater profit in working it. But cordage must certainly be stronger in proportion as there is more hemp and less tar in it, provided there is a sufficient quantity of the latter to unite the fibres. An oil extracted from the seeds of hemp is used in cookery in Russia, and by prisoners in this country. The seeds themselves are reckoned a good food for poultry, and are supposed to occasion hens to lay a greater quantity of eggs. Small birds in general are very fond of them, but they should be given to caged birds with caution and mixed with other seeds. A very singular effect is recorded, on very good authority, to have been sometimes produced by feeding bullfinches and goldfinches on hempsed alone, or in too great quantity — that of changing the red and yellow on those birds to a total blackness.

5934. *The hemp has few or no diseases.*

Synonym. 3. *The Fuller's Thistle, or Tassel* — *Dipsacus fulidum* L., *Tetrándria Monogynia* L., and *Dipsacæe* J. Chardon à foulon, Fr., Kardendistel, Ger., Danco, Ital. and Cardencha, Span. (fig. 799)

5935. *The fuller's thistle* is an herbaceous biennial growing from four to six feet high prickly or rough in the stem and leaves, and terminated by rough burr-like heads of flowers. It is a native of Britain, flowers in July and ripens its seed in September. It is cultivated in Essex and the west of England for raising the nap upon woollen cloth, by means of the crooked awns or chaffs upon the heads, which in the wild sort, are said to be less hooked. For this purpose they are fixed round the circumference of a cylinder which is made to turn round, and the cloth is held against them. In the *Journal of a Naturalist* we are informed that the tassel forms an article of culture in cottage gardens in the clothing districts of Gloucestershire.

5936. *There are no varieties of the cultivated tassel and the wild species is not materially different from it, and may be used in its stead, though its chaff is not quite so rigid.*

-99

5937. *The soil on which the tassel grows strongest are deep loamy clays, not over rich. The situation should be rather elevated airy and exposed to the south. In a rotation it may occupy the place of a green and corn crop as in the first year the plants are treated like turnips and in the second the crop is ripened. The soil should be ploughed deep and well contaminated by cross-ploughing, or stirrings with pronged implements, as the cultivator.*

5938. *The sowing season is the beginning of April the quantity of seed is from one peck to two pecks per acre, and in quality it should be fresh and plump.*

5939. *The mode of sowing is almost always broad cast, but no crop is better adapted for being grown in drills, as the plants require hoeing and thinning. The drills may be either sown on ridges or a flat surface, in the manner of turnips, or by ribbing. The distance between the rows may be from eighteen inches to two feet. In Essex caraway is commonly sown with the tassel-crop but this is reckoned a bad plan.*

5940. *The after-culture of this crop consists the first year in hoeing and stirring the soil, and in thinning out the plants to the distance of one foot every way if sown broad-cast, or to the distance of six inches if sown in rows. Vacancies may be filled up by transplanting and a separate plantation may be made with the thinnings, but these never attain the same vigour as the seedlings. The culture in the second year consists also of hoeing, stirring and weeding till the plants begin to shoot.*

5941. *When the tassel is grown broad-cast the intervals between the plants are dug by means of spades which have long narrow blades, not more than about four inches in breadth having the length of sixteen or eighteen inches. With these the land is usually worked over in the intervals of the plants three or four times during the summer months; and in the course of the following winter as about the latter end of February the land between the plants is to be again worked over by the narrow spades, care being taken that none of the mould falls into the hearts of the plants. Again about the middle of May, when they begin to sprout, another digging over is given, the earth being raised round the root-stems of the plants, in order to support and preserve them from being blown down by the wind. Some cultivators perform more frequent diggings, that the ground may be rendered cleaner and more mellow; consequently the growth of the plants will be the more effectually promoted. This business, in Essex has usually the name of spudding, and is executed with great despatch by labourers accustomed to perform it.*

5942. *The taking of the tassel crop, when no regard is had for seed, commences about the middle of July, when the blossoms begin to fall from the top, or terminating heads of flowers.*

5943. *It is the best method to have the heads cut as they become ripe but the work is mostly executed at three times, at the distance of about ten days or a fortnight from each other. It is performed by means of a knife, modified for the purpose, with a short blade and a string attached to the haft. This last is done in order that it may be hung near the hand. A pair of strong gloves is likewise necessary. Thus prepared,*

the labourer cuts off the ripe heads along the rows or lines with about nine inches of stem, and ties them up in handfuls with the stem of one that is more perfectly ripened. On the evening of the day on which they are cut, they should be put into a dry shed; and when the weather is fine and the air clear, they should be taken out and exposed to the sun daily till they become perfectly dry. Much care must, however, be taken that no rain falls upon them. In doing this, some make use of long small stakes or poles, on which these handfuls are hung during the time of their preparation.

5944 *As soon as they are completely dried, they should be laid up in a dry room, in a close manner till they become tough and of a bright colour and ready for use. They should then be sorted or separated into three kinds, by opening each of the small bundles. These are distinguished into kings, middlings, and scrubs according to their different qualities. They are afterwards the author of The Somerset Report says made into packs, which of the first sort, contain nine thousand heads, but when of the second, twenty thousand, the third is a sort of very inferior value. By some, before forming them into packs, they are done up into what are termed staves, by means of split sticks, when they are ready for sale.*

5945 *The produce of teasel varies from ten to fifteen packs on the acre—nine packs of kings, nineteen of middlings and two of scrubs, are reckoned a large crop, with a great bulk of haulm. Often, however the crop fails.*

5946 *The use of the heads of the teasel has been already mentioned. The haulm is of no use but for burning as manure. Parkinson observes, that this is a sort of crop that may be grown to advantage on many lands, in a rotation as a fallow to prepare for wheat and by burning the straw and refuse stuff after the crop is reaped, it will be found not to impoverish, but rather to improve the land. In their young state, the teasel plants stand the winter without danger and are a good crop for clearing land of all weeds, from their lateness in the process of hoeing their being few weeds that vegetate at so advanced a season. On all these accounts they become an advantageous crop for the farmer.*

5947 *To save seed, leave a few of the very best plants uncropped and then, when the seed is ripe, cut off only the largest and terminating heads, from which the seed is easily separated by beating with flails, and cleaned by the winnowing machine or a sieve.*

5948 *The chief injuries to which the teasel is liable are those inflicted on it while young, by the fly and slug.*

Summary 4 Madder — *Rubia tinctorum* L. *Tetránthra Monogyna* L., and *Rubiacæ* J. Garance, Fr., Farberrotke, Ger., *Robia*, Ital. and *Rubia*, Span (fig 800)

5949 *The dyer's madder has a perennial root, and an annual stalk. The root is composed of many long, thick, succulent fibres, almost as large as a man's little finger—these are joined at the top in a head, like the roots of asparagus, and strike very deep into the ground, being sometimes more than three feet in length. From the upper part (or head of the root) come out many sideroots which extend just under the surface of the ground to a great distance whereby it propagates very fast for these send up a great number of shoots, which if carefully taken off in the spring soon after they are above ground become so many plants. It is a native of the south of Europe flowers in June, and seeds soon afterwards but by them it is never propagated. Madder is mentioned by the Greeks as a medical plant, but when it was first used in dyeing is uncertain. It has been cultivated in Holland and Flanders, and other parts of the Continent, for the latter purpose for many centuries, and has been tried in this country but unless the importation of the root from the Continent be entirely prevented it will not answer. Its culture has been attempted at different times when our commerce with the Dutch was interrupted, or when they raised the price of the article exorbitantly high. At present it may be imported not only from Holland, but from France, Italy, and Turkey.*

5950 *The soils most suited to the cultivation of madder are deep, fertile sandy loams, not retentive of moisture, and having a considerable portion of vegetable matter in their composition. It may also be grown on the more light descriptions of soil, of sufficient depth, and in a proper state of fertility.*

5951 *The preparation of the soil may either consist in trench ploughings, lengthwise and across, with pronged stirrings so as to bring it to a fine tilth or what will often be found preferable, by one trenching two feet deep by manual labour.*

5952 *The sets or plants are best obtained from the runners, or surface-roots of the old plants. These being taken up, are to be cut into lengths of from six to twelve inches, according to the scarcity or abundance of runners. Sets of one inch will grow if they have an eye or bud, and some fibres but their progress will be injuriously slow for want of maternal nourishment. Sets may also be procured by sowing the seeds in fine light earth a year before they are wanted, and then transplanting them or sets of an inch may be planted one year in a garden, and then removed to the field plantation.*

5953. The season of planting is commonly May or June, and the manner is generally in rows nine or ten inches asunder and five or six inches apart in the rows. Some plant promiscuously in beds with intervals between, out of which earth is thrown in the lazy bed manner of growing potatoes but this is unnecessary as it is not the surface, but the descending roots which are used by the dyer.

5954. The operation of planting is generally performed by the dibber but some lay-plant them by the aid of the plough. By this mode the ground is ploughed over with a shallow furrow and in the course of the operation the sets are deposited in each furrow leaning on and pressed against the furrow-slice. This, however is a bad mode, as there is no opportunity of firming the plants at the roots, and as some of the sets are apt to be buried, and others not sufficiently covered.

5955. The after-culture consists in hoeing and weeding with stirring by pronged hoes, either of the horse or hand kind. Some earth up, but this is unnecessary and even injurious, as tearing the surface-roots.

5956. The madder-crop is taken at the end of the third autumn after planting, and generally in the month of October. By far the best mode is that of trenching over the ground, which not only clears it effectually, but fits it at once for another crop. Where madder, however has been grown on land prepared by the plough, that implement may be used in removing it. Previously to trenching, the haulm may be cleared off with an old scythe and carted to the farmyard to be used as litter to spread in the straw yards.

5957. Drying the roots is the next process, and, in very fine seasons, may sometimes be effected on the soil by simply spreading the plants as they are taken up but in most seasons they require to be dried on a kiln like that used for malt or hops. They are dried till they become brittle, and then packed up in bags for sale to the dyer.

5958. The produce from the root of this plant is different according to the difference of the soil, but mostly from ten to fifteen or twenty hundred weight when they are suit-able to its cultivation.

5959. In judging of the quality of madder-roots, the best is that which on being broken in two, has a brightish red or purplish appearance, without any yellow cast being exhibited.

5960. The use of madder-roots is chiefly in dyeing and calico-printing. The haulm which accumulates on the surface of the field, in the course of three years, may be carted to the farm yard and fermented along with horse-dung. It has the singular property of dying the horns of the animals who eat it of a red colour.

5961. Madder-seed in abundance may be collected from the plants in the September of the second and third years but it is never so propagated.

5962. Madder is sometimes blighted; but in general it has few diseases.

**SUBJECT 5. Woad** — *Isatis tinctoria* L.; *Tetradymus Sibyrus* L. and *Crucifera* J. *Pastel* or *Gualde*, Fr., *Woad* Ger. *Gualde*, Ital., and *Gualdo*, Span. (fig. 801.)

5963. The common woad is a biennial plant with a fusiform fibrous root, and smooth branched stem rising from the root to five feet in height. It is a native, or naturalised in

England, flowers from May to July and its seeds are ripe from July to September. It has been cultivated in France for an unknown length of time, and was introduced to England in 1582, and grown with success. It is now chiefly cultivated in Lancashire, where it is a common practice to take rich flat tracts near rivers, at a high price, for the purpose of growing it for two or four years. Those who engage in this sort of culture form a sort of colony, and move from place to place as they complete their engagements. It is sometimes, however grown by stationary farmers. The leaves are the parts of the plant used and it is considered a severe crop.

5964. There is a variety of woad called the Dalmatian, described by Miller and also a wild sort but only the common is cultivated in this country.

5965. The soil for woad should be deep and perfectly fresh, such as those of the rich, mellow loamy and deep, vegetable kind. Where this culture is carried to a considerable degree of perfection, as in Lancashire, the deep rich, peaty, alluvial soils on the flat tracts extending upon the borders of the large rivers, are chiefly employed for the growth of this sort of crop, and it has been shown by repeated trials that it answers most perfectly when they are broken up for it immediately from a state of sward.

5966. The preparation of the soil, when woad is to be grown on grass land, may either be effected by deep ploughings, with the aid of the winter's frost, cross ploughing and

harrowing in spring, by deep ploughing and harrowing in spring by paring and burning, or by trench ploughing, or spade trenching

5967 *The first mode appears the worst*, as it is next to impossible to reduce old turf in one year and even if this is done, the danger from the grub and wire-worm is a sufficient argument against it. By ploughing deep in February and soon afterwards sowing the plants may germinate before the grub is able to rise to the surface, by trench ploughing the same purpose will be better attained and, best of all by spade trenching. But a method equally effectual with the first, more expeditious, and more destructive to grubs, insects and other vermin which are apt to feed on the plants in their early growth is that of paring and burning. This is however chiefly practised where the sward is rough and abounds with rushes sedge and other plants of the coarse kind, but it might be had recourse to on others, with benefit.

5968. *The time of sowing* may be extended from February to July. Early sowing however, is to be preferred, as in that case the plants come up stronger and afford more produce the first season.

5969 *The mode of sowing* is generally broad-cast, but the plant might be most advantageously grown in rows and cultivated with the horse-hoe. The rows may be nine inches or a foot apart, and the seed deposited two inches deep. The quantity of seed for the broad-cast method is five or six pounds to the acre for the drill mode, two pounds are more than sufficient, the seed being smaller than that of the turnip. New seed, where it can be procured, should always be sown in preference to old but, when of the latter kind, it should be steeped for some time before it is put into the ground.

5970 *The after-culture* of the woad consists in hoeing thinning, prong-stirring, and weeding which operations may be practised by hand or horse tools, as in the culture of teasle.

5971 *Gathering the crops.* The leaves of the spring sown plants will generally be ready towards the latter end of June or beginning of July according to the nature of the soil season and climate the leaves of those put in at a later period in the summer are often fit to be gathered earlier. This business should however, constantly be executed as soon as the leaves are fully grown while they retain their perfect green colour and are highly succulent as when they are let remain till they begin to turn pale much of their goodness is said to be expended, and they become less in quantity, and of an inferior quality for the purposes of the dyer.

5972. *In the execution of this sort of business* a number of baskets are usually provided in proportion to the extent of the crop, and into these the leaves are thrown as they are taken from the plants. The leaves are detached from the plants, by grasping them firmly with the hand, and giving them a sort of a sudden twist. In favourable seasons where the soils are rich the plants will often rise to the height of eight or ten inches but in other circumstances they seldom attain more than four or five and where the lands are well managed they will often afford two or three gatherings, but the best cultivators seldom take more than two, which are sometimes mixed together in the manufacturing. It is necessary that the after-croppings, when they are taken, should be constantly kept separate from the others, as they would injure the whole if blended, and considerably diminish the value of the produce. It is said that the best method, where a third cropping is either wholly or partially made, is to keep it separate forming it into an inferior kind of woad.

5973. *The produce* is mostly from about a ton to a ton and a half of green leaves. The price varies considerably but for woad of the prime quality it is often from twenty five to thirty pounds the ton, and for that of an inferior quality six or seven and sometimes much more.

5974 *To prepare it for the dyer* it is bruised by machinery to express the watery part it is afterwards formed into balls, and fermented, re-ground, and fermented in vats, where it is evaporated into cakes in the manner of indigo. The haulm is burned for manure or spread over the straw yard, to be fermented along with straw dung.

5975 *The use of woad in dyeing* is as a basis for the black and other colours.

5976 *To save seed*, leave some of the plants undenuded of their leaves the second year and when it is ripe, in July or August, treat it like turnip-seed.

5977 *The only diseases* to which the woad is liable are the mildew and rust. When young it is often attacked by the fly and the ground obliged to be re sown and thus more than once even on winter ploughed grass lands.

SUNSHOT 6 *Weld, or Dyer's Weed* — *Reseda luteola* L. *Dodecatheon Triflorum* L.  
and *Resedifera* Lindl. *Gaulth.* Fr *Woad* Ger (fig 802)

5978. *Weld* is an imperfect biennial, with small fusiform roots, and a leafy stem from one to three feet in height. It is a native of Britain, flowers in June and July, and ripens its seeds in August and September. It is cultivated in a few places in England, and chiefly in Essex, for its spike of flowers, and sometimes also for its leaves both of which are used in dyeing. Its culture may be considered the same as that of woad, only being a smaller plant it is not thinned out to so great a distance. It has this advantage for the farmer over all other colouring plants, that it only requires to be taken up and dried, when it is fit for the dyer. It is, however an exhausting crop.

5979 *Weld will grow on any soil*, but fertile loams produce the best crops. In Essex, it is grown on a stiff loam, moderately moist.

5980. The soil being brought to a fine tilth, the seed is sown in April or the beginning of May generally broad-cast. The quantity of seed is from two quarts to a gallon per acre, and it should either be fresh, or, if two or three years old, steeped a few days in water previously to being sown. Being a biennial, and no advantage obtained from it the first year it is sometimes sown with corn crops in the manner of clover, which when the soil is in a very rich state may answer provided that hoeing, weeding, and stirring take place as soon as the corn crop is cut. The best crops, however will obviously be the result of drilling and cultivating the crop alone. The drills may be a foot asunder and the plants thinned to six inches in the row. In the broad-cast mode, it is usual to thin them to six or eight inches distance every way. Often, when woad succeeds corn crops, it is never either thinned, weeded, or hoed, but left to itself till the plants are in full blossom.

5981. The crop is taken by pulling up the entire plant and the proper period for this purpose is when the bloom has been produced the whole length of the stems, and the plants are just beginning to turn of a light or yellowish colour as in the beginning or middle of July in the second year. The plants are usually from one foot to two feet and a half in height. It is thought by some advantageous to pull it rather early without waiting for the ripening of the seeds as by this means there will not only be the greatest proportion of dye, but the land will be left at liberty for the reception of a crop of wheat or turnips in this case, a small part must be left solely for the purpose of seed.

5982. In the execution of the work the plants are drawn up by the roots in small handfuls and after each handful had been tied up with one of the stalks, they are set up in furs in an erect position and left to dry. Sometimes, however they become sufficiently dry by turning without being set up. After they have remained till fully dry which is mostly effected in the course of a week or two, they are bound up into larger bundles, each containing sixty handfuls, and weighing fifty-six pounds. Sixty of these bundles constitute a load, and, in places where this kind of crop is much grown, are tied up by a string made for the purpose, which is sold under the title of woad cord.

5983. The produce of woad depends much on the nature of the season but from half a load to a load and a half per acre is the quantity most commonly afforded. It is usually sold to the dyers at from five or six to ten or twelve pounds the load, and sometimes at considerably more. It is mostly bought by persons who afterwards dispose of it to the dyers. The demand for it is sometimes very little, while at others it is so great as to raise the price to a high degree. It is sometimes gathered green and treated like woad or indigo but in general the dried herb is used by the dyers in a state of decoction.

5984. The use of woad in dyeing is for giving a yellow colour to cotton woollen, mohair, silk, and linen. Blue cloths are dipped in a decoction of it which renders them green and the yellow colour of the paint called Dutch pink is obtained from woad.

5985. To raise seed, select a few of the largest and healthiest plants, and leave them to ripen. The seed is easily separated.

5986. The chief disease of woad is the mildew, to which it is very liable when young, and this is one reason that it is often sown with other crops.

**SUSSEX 7. Bastard Saffron.** — *Carthamus tinctivus* L. *Syngendula Polygamia* *Equalis* L. and *Cynarcephala* J. *Carthamus* Fr. *Wilder Saffron*, Ger. (fig 140 p. 174.)

5987. The bastard saffron is an annual plant, which rises with a stiff ligneous stalk, two feet and a half or three feet high, dividing upwards into many branches, with ovate pointed sessile leaves. The flowers grow singly at the extremity of each branch the heads are large, enclosed in a scaly calyx each scale is broad at the base, flat, and formed like a leaf of the plant, terminating in a sharp spine. The lower part of the calyx spreads open, but the scales above closely embrace the florets, which stand out nearly an inch above the calyx these are of a fine saffron colour, and this is the part which is gathered for the use of the dyer.

5988. It grows naturally in Egypt and some of the warm parts of Asia; but, being an annual, our summer admit of its going through a course of existence in this country. Sown in April, it flowers in July and August, and the seeds ripen in autumn, but if the season proves cold and moist, when the plants are in flower there will be no good seeds produced; so that there are few seasons wherein the seeds of this plant come to perfection in England.

5989. It is cultivated in great plenty in Germany and was formerly grown in England. In *Houghton's Collections*, it is related by a gentleman, in 1684, that twenty five acres in the Vale of Evesham, in Gloucestershire, were sown with this seed; the soil a mixed sand of about fifteen shillings an acre in value. It bore a crop of wheat the year before, was dressed for barley and had a harrowing extraordinary. This piece of ground was taken six years by an adventurer in this seed, at the rate of twenty five pounds per acre in consideration that this plant is said to be a great improver of land. He sold the flowers in London for 1½ per pound; a price, he said, much below his expectation. He gained above thirty shillings an acre clear profit, except the price of the seed; but of this there was a plentiful return (about one hundred and sixty bushels) which, had it been well managed, would have amounted to a considerable value. Like

most other manufactory plants it is considered an impoverisher of the ground both by exhausting it, and by affording but little bacin as manure.

5990. *The soil it requires is light, and the preparation and culture, according to Von Thier equal to that of the garden. The seed is sown in rows, or deposited in patches two feet apart every way and when the plants come up they are thinned out, so as to leave only two or three together. The soil is stirred and weeded during summer. In August the flowers begin to expand the petals of the florets are then to be cut off with a blunt knife, and dried in the shade, or on a kiln like the true saffron. This operation is performed in the early part of the day and continued daily till October. The plants are then pulled up, sheaved and shocked, and threshed for their seed.*

5991 *The use of the flower of bastard saffron is chiefly in dyeing. It is also put in soups, pies, and puddings, like the leaves of the marigold or the common saffron. The oil produced from the seed is used both in medicine and painting. The stalks of the plants are commonly burnt for manure.*

SUBJECT 8 *Various Plants which have been proposed as Substitutes for the Thread and dyeing Plants grown in Britain.*

\*5992. *Though few of these are likely to come into cultivation, yet it may be useful to notice them, with a view to indicating our resources for extraordinary occasions to leading the young cultivator to reflect on the richness of that immense store-house the vegetable kingdom and to pointing out sources of experiment and research for the amateur agriculturist. Every kind of limitation has a tendency to degrade the mind, and lessen enterprise. The plants to be here enumerated, naturally arrange themselves as thread plants and colouring plants.*

5993. *The thread plants that have been tried are the *Asclepias syriaca*, *Urtica dioica* (or nettle), *Urtica canadensis* (or nettle), the *Spartium fuscum* and *Cytisus scoparius* (broom), *Epilobium angustifolium*, *Eriophorum polystachyon*, &c. The *Asclepias syriaca*, Syrian swallow wort, or *V. virginica* still, is a creeping rooted perennial, with strong erect stems from four to six feet high. It is a native of Virginia, and flowers in July. The flowers are succeeded by pods, containing a down or cotton which the poor people in Virginia collect and fill their beds with. In Germany and especially at Leignitz attempts were made, in 1790 and 1800, Von Thier informs us, to cultivate the plant as a substitute for cotton. It was found to grow readily on a poor soil; but the growers could not undersell the importers, nor produce so good an article. The *Eriophorum polystachyon*, or cotton grass grows abundantly in our bogs and its seeds are furnished with a cottony substance, gathered by the country people to stuff pillows &c. This substance has been spun and woven into very good cloth. The common nettle affords a fibre which has also been spun and manufactured. The fibre of the *Spartium fuscum*, rush-like, or Spanish broom a native of the south of Europe, but quite hardy in Britain, is made into very good cloth both in the south of France and in Spain. The fibre of the common broom makes an inferior description of cordage in the former country. The *Epilobium angustifolium* and other species of willow herb common by the side of brooks, afford a very good fibre as do a great variety of plants and in Sweden a strong cloth is made from the stems of the wild hop (*Humulus lupulus*) and the same thing has been done in England. (*Trans. Soc. Arts* 1791.) Indeed there are few plants the fibres of which might not be separated and rendered available for the purpose of spin up threads for weaving into cloth or of mashing for making paper. The fibres of all nettles and square-stalked herbaceous plants answer for the former purpose: not both the fibres and bark of several plants, for the latter. The fibres of all the herbaceous stalks we are uncommonly white, and finer than camel's hair and in Germany they are used in making an imitation of India paper for engraving. The filaments of the common field-bean are among the strongest yet discovered these, with a little beating, rubbing, and shaking, are easily separated from the straw part, when the plant has been steeped ten or twelve days in water or in damp, and in a state approach ing to fermentation or what is commonly called retting. Washing or pulling it through heckles or iron combs, first coarse, and then finer is necessary to the dressing of bean hemp, and is perhaps the easiest mode of separating the filaments from the thin membrane that surrounds them. The fibre of the common nettle is very similar to that of hemp or flax, differing only according to the soil and different situations in which it grows and it has been shown by experiment, that they may be used for the same purposes as hemp or flax, from cloth of the finest texture down to the coarsest quality, such as uni-cloth, sack cloth, &c. (*Smith's Mechanic* vol. II.) It might be worth the attention of any one who had leisure to collect a few say only two, stalks, of a great number of species from a botanic garden to immerse them a sufficient time in soft soap and warm water and prove their absolute and comparative value as fibre plants.*

5994. *Bean flax is prepared by steeping the twigs or most viscous shoots of the former year, for two or three weeks, in warm water, according to the heat of the season, in stagnant water or by boiling them for about an hour in water. This done the flax comes freely from the twigs; and where there is not machinery for the purpose, may be easily peeled or stripped off by hand or others at any time when not quite dry, in the same way as hemp is peeled from the stalks. Being cleared of the flax, and steeped for some time in boiling water, the twigs, or wood, becomes tough and beautifully white and is worth, at a medium from shilling to eighteen-pence per pound, for making carpet brooms, &c. When stripped from the twigs, the flax requires only to be well washed in cold water, then wrung and shaken well and hung out to dry previously to its being sent off to the paper manufacturers. (*Smith's Mechanic*, vol. II.)*

5995. *Of colouring plants, the number that may be, and even are employed, is almost endless. The reader has only to look into any botanical catalogue, and observe the number of plants whose specific names are termed from the adjective tinctorius and these though numerous, are still only a small part. On looking into the *Flore Belvédère*, or *Flore Boissier* he will there find a number of plants, trees, and even mosses and ferns used for dyeing. A number have been tried in this country and given up, as an instance, we mention *Gallium verum* which, in 1780, when the price of madder was high, was tried under the authority of the privy council for trade. The *Croton tinctorius*, *Genista tinctoria*, *Rhamnus cathartica* and *Infusoria*, and *Plantago Psyllium*, are cultivated in France as dyeing plants.*

SECT. II. *Plants cultivated for the Brewery and Distillery*

5996 *Of plants grown expressly for their use in the brewery the only one of consequence is the hop, the anis and caraway are grown on a very limited scale for the distillery*

**SUBJECT 1 The Hop.**—*Humulus Lupulus* L.; *Durcila Pentadactyla* L., and *Urtica* J. Houbton, Fr.; *Hoppen*, Ger. *Lupolo*, Ital. and *Lupulo*, Span. (fig 808)

5997 The hop is a perennial-rooted plant with an annual twining stem, which, on poles or in hedges, will reach the height of from twelve to twenty feet or more. It is a native of Britain and most parts of Europe, in hedges, flowering in June and ripening its seeds in September. The female blossom is the part used and as the male and female flowers are on different plants, the female only is cultivated.

5998 When the hop was first used for preserving beer or cultivated for that purpose is unknown; but its culture was introduced to this country from Flanders in the reign of Henry VIII. Walter Blith in his *English Improver Improved* 1649, the third edition 1653, p. 240 has a chapter upon improvement by plantations of hops &c. He observes that "hops were then grown to be a national commodity but that it was not many years since the famous city of London petitioned the parliament of England against two annualities and these were Newcastle coals, in regard to their stench &c. and hops in regard they would spoil the taste of drink, and endanger the people and had the parliament been so wiser than they are now, it would have been a great service to the realm."

we had been in a measure paid and in a great measure are starved which is not answerable to the pain and expense of those men who cry down all devices or ingenious discoveries as projects, and thereby stifle and choke improvements.

5999 The hop has long been cultivated extensively in many parts of England but not much in Scotland or Ireland. According to Brown hops are not advantageous in an agricultural point of view because much manure is abstracted by them while little or none is returned. They are an uncertain article of growth, often yielding large profits to the cultivator and as often making an imperfect return barely sufficient to defray the expenses of labour. In fact, hops are exposed to more diseases than any other plant with which we are acquainted and the trade affords a greater room for speculation than any other exercised within the British dominions. Brown Parkinson in a paper on the culture of the hop in Nottinghamshire published in the *Farm. Mag.* vol. xvi. observes that "the hop is said to be a plant very properly named, as there is never any certainty in cultivating it."

6000 There are several varieties of the hop. The writer of *The Synopses of Husbandry* distinguishes them under the titles of the Flemish the Canterbury the Goldwage, the Farnham, &c. and says that the Flemish is held in the lowest estimation of any

6001 The Flemish hop, he says, is of a smaller size, of a much closer texture, and of a darker green colour than any of the rest, and grows on a red bind and has so near an affinity to the wild or hedge-hop, that it would never answer for cultivation did it not possess the property of resisting the blast with greater vigour than the other kind. In those years when these last are covered with dews and fogs the Flemish hop appears strong and healthy. At picking time likewise this kind of hop he says, takes less damage either by the sun or rain than any other and upon these accounts, it may answer the views of the planter to have a few acres of it, which will secure him a crop in a blinding season, when those of the more valuable glass are destroyed, so as to be worth nothing.

6002 The soils most favourable to the growth of hops are clays and strong deep loams but it is also of great importance that the subsoil should be dry and friable a cold wet, tenacious, clayey understratum being found extremely injurious to the roots of the plants, as, when they penetrate below the good soil, they soon become unproductive and ultimately decay.

6003 A chalky soil, Bannister says, is, of all others, the most inimical to the growth of this vegetable; the reason of which he takes to be the dry and parching quality of the chalk by which the roots are prevented from absorbing a quantity of moisture, equal to the supply to the vine or bind with sap during its growth. For though a drying summer is by no means kindly to the welfare of the hop, yet a vine in a healthy state is very luxuriant, and furnished with a large abundance of branches, leaves, fruit, &c. it follows that the demand of moisture from the soil must be proportionably great to preserve the plant in health and vigour and for this reason the ground ought not to be deficient in natural humidity. Hence we generally find the most luxuriant vine growing on deep and rich soils and mould &c. and in these grounds it is common, he says, to grow a load on an acre. But it is to be observed, however that the abundance of fruit is not always in proportion to the length of the vine. On those soils which from their fertility, cause a large growth of vine are more frequently attacked by the blast, than land of a shallower staple where the vine is weaker and less luxuriant.

6004 But though rich moulds generally produce a larger growth of hops than other soils there is one exception to this rule, where the growth is frequently eighteen or twenty hundred per acre. This is on the rocks in the neighbourhood of Maidstone in Kent a kind of stony ground, with an understratum of stone. On these rocks there is a large extent of hop-garden where the vines run up to the tops of the longest poles, and the increase is equal to that on the most fertile soil of any kind.

6005 The most desirable situation for a hop plantation is ground sloping gently towards the south or south west, and screened by means of high grounds or forest trees from the north and north east. At the same time it ought not to be so confined as to prevent that free circulation of air which is necessary where plants grow so close together and to such a height. A free circulation of air is a high ground, not only conducive to the health and vigour of the plants, but also prevents the crops from being blighted or what the hop-farmers call fire-blasted which often happens towards the middle of a very close planted hop-ground while the outside, in consequence of the more free circulation of air that it receives, takes place, requires no injury whatever.

6006 Bannister asserts, that those fields which lie within a few miles of the sea or in the neighbourhood of marshy or swampy levels, are seldom favourable to the growth of hops, as such grounds generally suffer in a blinding year and though from the fertility of the soil, they may perhaps bring a plentiful crop in those seasons when the growth is general such a situation is eligible for a hop ground in Worcestershire and Herefordshire hops are very generally grown between the row of fruit trees in dug or ploughed orchards.

6007 *In preparing the soil previously to planting, considerable attention is necessary, by fallowing, or otherwise, to destroy the weeds, and to reduce the soil to as pulverised a state as possible. The ridges should also be made level, and dung applied with a liberal hand. The most effectual preparation is trenching either by the plough or by manual labour.*

6008 *The mode of planting is generally in rows, making the hills six feet distant from each other though there are some people who, from avaricious motives, prefer a five-foot plant. But as this vegetable, when advanced in growth produces a large redundancy of bind or vine and leaves, it should seem that six feet cannot be too wide a distance and that those which are planted closer will, from too confined a situation be prevented from enjoying a free circulation of the air from which much injury may proceed, as blights, mildews moulds and other accidents, not to mention the disposition of the vine to house or grow together at the tops of the poles, whereby the hops are so overshadowed as to be debarr'd the influence of the sun, and prevented from arriving at half their growth.*

6009 *As the planters differ as to the number of hills to be made on the same given quantity of land, so are they no less capricious as to the manner of placing them some choosing to set them out with the most exact regularity in rows of equal distances, whilst others prefer planting in quincunx. The former method has this advantage that the intervals may in the early part of the summer be kept clean by means of the cult vator and harrow but, in the latter method these implements are rendered inadmissible by the irregular station of the plants; and the ground must be tilled with the hoe at a greatly increased expense as the same labour might be performed to as much advantage with one horse a man and a boy who will do more work in a day than half a dozen labourers can with a hoe.*

6010 *The ordinary season for planting is spring in February or March but if bedded plants, or such as have been nursed for one summer in a garden are used, then by planting in autumn some produce may be had in the succeeding year. But, according to the author of *The New Farmer's Calendar* the time for planting is commonly that of dressing and pruning the old vines when cuttings may be had which is in March or April but when root-sets are used as on the occasion of grubbing up an old plantation October to the beginning of November. But at whatever period they are planted, great care should be taken that the same sorts be planted together as by this means there are advantages derived in their after culture.*

6011 *The plants or cuttings are procured from the old stools, and each should have two joints or eyes from the one which is placed in the ground springs the root and from the other the stalk provisionally the bind. They should be made from the most healthy and strong binds each being cut to the length of five or six inches. Those to be nursed are planted in rows a foot apart, and six inches asunder, in a garden and the others at once where they are to remain.*

6012 *The mode of performing the operation of planting in Kent is as follows —*

6013 *The land having been previously cleaned and prepared, dung is laid on the field in small heaps near the places where it is proposed to plant the hop slips or sets. These places are commonly marked off by infixing a number of stakes at proper and regular distances that deep small pits are formed by taking out a spit, or spade's depth of earth and the earth below being gently loosened a certain quantity about half a bushel of dung is laid therein then the earth that was formerly taken out again replaced and so much added as to form a small hillock. On this hillock five, six or even sets procured from roots or shoots of the old stock, are dibbled in. The plants are placed in a circular form towards the top of the hillock, and at the distance of five or six inches from each other. They are made to incline towards the centre of the hillock where another plant is commonly placed.*

6014 *Another mode of planting is as follows —Strike furrows, with the plough at equal distances of eight feet when finished, repeat the same across in the opposite direction which will divide the piece into eight-foot squares. The hills are to be made where the furrows cross each other and the horse-hoe may be admitted between the rows both ways. According to the Suffolk husbandry the plantations are formed into beds sixteen feet wide, by digging trenches about three feet wide and two or three feet deep the earth that comes out being spread upon the beds and the whole dug and levelled. Upon this they in March form the holes six feet asunder every way twelve inches diameter and a pit deep by which three rows are formed on each bed. Into each hole they put about half a peck of very rotten dung or rich compost, and scatter earth upon it and in each they plant a set, drawing earth enough to it afterwards to form something of a hillock.*

6015 *An interval crop is generally taken in the first summer of a hop plantation. Beans are very generally grown and Bannister is of opinion that two rows of beans may be planted in each interval without any damage to the hops, whether bedded sets or cuttings. In the latter case, this method may be pursued in the second year at the end of which the vine from the cuttings will not be in a more forward state than that from the bedded sets in the first autumn after planting. Others, however think that neither beans, cabbages, nor any other plants, except onions, should be put in.*

6016 *The after-culture of the hop besides the usual processes of hoeing, weeding stirring and manuring includes earthing-up, staking and winter dressing.*

6017 *Hoeing in hop plantations may always be performed by a horse implement, and one in use for this purpose in the hop counties and of which the expanding horse hoe *fig. 35* is an improved one, is known by the name of hop-hedge. When the hop-stools are formed in the angles of squares the intervals may be hoed both lengthwise and across, and thus nothing is left to be performed by manual labour but pulling out any weeds which may rise in the hills.*

6018 *Stirring, in the hop districts, is chiefly performed in winter with a three pronged fork (provisionally spud) but it might be equally well effected then or at any season of the year with the common plough and the expanding horse-hoe set with coulter or prongs. With the latter implement the soil might be stirred to any desirable depth either in summer or winter, and with the plough, the surface could be changed at discretion. Once going and returning would suffice, either by the paring or clearing out.*

that is, during either a night, or gutter between the rows, both lengthwise and across. Twice or thrice going in the same direction would also succeed, and would be the preferable mode of covering in manure (6010). On the application of manure various modes are adopted. Some always use well rotted stable dung; others, composts of earth and dung, and a few literary dung. In laying it on, many prefer the autumn to the spring, and heap it on the hills without putting any between the rows. Others put it all between the rows, alleging that laying it on the hills encourages insects, exposes the dung to evaporation and loss, and sometimes, when mixed with earth, hinders the plants from coming up. A great deal will be found in favour of, and against each of these modes, in the numerous works on the culture of the hop, which have been written during the last three centuries; but it must be obvious to any person generally conversant with vegetable culture, that well rotted stable dung must be the best kind for use, and early in spring the best season for laying it on; that little benefit can be derived by the roots when it is laid on the hills, and consequently that it ought to be turned into the soil between the rows by the plough. Fifty cart-loads of dung and earth, or thirty of dung, once in three years, is reckoned a good dressing, but some give ten or twelve loads every year. Too much dung renders the hops what is called moulty, and too little causes the crop to be poor and more liable to be eaten by insects.

6021. *Earthing-up* commences the first May after planting, whether that operation be performed in spring or autumn. By the end of the spring season, the young shoots have made some progress, and the earth is then drawn up to their roots from the surrounding intervals, in order to strengthen them. The next earthing-up is in autumn, when the hills are by some covered with compost or manure, but by such as prefer ploughing in the manure between the rows, this earthing-up is not given. Some give an earthing-up of this kind in spring, and generally in February, chiefly to reward the plants, as that is found to render them less liable to disease, and the attacks of insects; for the shoots not beginning to grow till the weather is warm, they then shoot more rapidly. In April and May their progress is slow, but in June and July when the nights are warm, they will grow nearly an inch in the hour. The only essential earthing-up, however, are those given the first year in May and those given annually after the operation of drawing, whether in autumn or spring, which indeed may be called raking of earth, rather than earthing-up.

6022. In *dressing the hop plants*, the operations of the first year are confined to twisting and removing the haulm, to which some add cuping or earthing-up in autumn.

6023. The operation of *twisting* is confined to such plants as have been planted in spring, and are not expected to produce any crop that season. It is performed in the last of June or July, and consists in twisting the young vines into a bunch or knot; so that, by thus discouraging their growth, the roots are enabled to grow out more vigorously, and to stretch upwards previously to the approach of the winter season.

6024. *Removing the haulm* takes place soon after Michaelmas and consists simply in cutting it off with a scythe, and carrying it off the field for litter or burning. After this operation some add cuping, or covering the hill with compost, but this does not succeed better, and is in many cases left undone.

6025. The first year's *drawing* of hops expected to produce flowers, such as those planted from bedded sets, is the preceding autumn, consists in stripping three or four haulms, that is, the poles of four or five feet in length to each hill, and on removing the haulm in autumn, as in the other cases.

6026. The yearly *drawing* of established hop plantations consists of what is particularly called *picking*. This operation is generally commenced towards the end of April, or at whatever period, earlier or later, the shoots may have risen two or three inches.

6027. The poles are straight slender shoots of waterwood, ash, elm, chestnut, or willow, from sixteen to twenty feet high. These poles are set two, but more frequently three, to a hill; and are so placed as to leave an opening towards the south, to admit the sunbeams. The manner of fixing them is by making deep holes or openings in the ground with an iron crow. Into these holes the root-ends are put, when the earth is rammed as hard about them as that they may seldom stir from the position in which they were placed, except on occasions of very violent gusts of wind. Great care is necessary in placing the poles, and no less judgment and experience in determining what ought to be the proper height. When very long poles are set in a hop-ground, where the stocks are too old or too young, or where the soil is of insufficient quality the stocks are not only greatly exhausted, but the crop always turns out unproductive, as the vines reach the top, or rather till they overtop the poles, which depends on the strength of the poles and the quality of the soil the lateral branches on which the hops grow never begin to shoot out, or make any progress.

6028. *Planters are much divided in their sentiments as to the number of poles to be set against each hill.* Those poles are the general allowance, observing to place the utmost pole to the south-west aspect of the hill (though it is no uncommon practice to set four poles, and an strong level five or six, to a hill. In behalf of this latter mode it is urged, that, when the land usually produces a good redundancy of it, it is prudent to set a number of poles according to the luxuriance of the shoots. But, if this circulation of the air be matter of such importance to the well-being of crops of hops as is generally imagined (and this is a doubtful whole, it is believed cannot be controverted) the accumulating of the hills with an additional number of poles cannot fail to be of infinite dis-service to the future growth of the hops; and it will be readily acknowledged that the quantity of hops on the same given number of hills will be quite considerably more where three poles only are set up, than where the hills are covered with a larger number, whether we consider the material likely to accrue from the designated air, or from the reduction of the weight of the hills, or the more wanted from arising to their proper size or growth. The best way is putting hop-grounds in first, to pitch the hills to a proper height, about twenty inches in the pole with some surplus of strength, so that being well sharpened it may be thrust freely at the bottom (which, that the tops of the poles are staked in such a direction as to lean upwards from the hill, so as to prevent, as much as possible, the blowing of the wind, and finally to crowd the earth close to the pole with the foot. For want of this the vines sometimes in the winter a more or a blast of wind will break the poles, so as not only to occasion double expense, but the hazard of injuring the future crop by sending upwards the vines, which, from the great transpiration will become too weak together, or so as to be severed, hence at the cessation of the crop.

6029. With regard to the space of yards proper for poles, it is supposed that the hop-grounds to be set a rough and level, in one which is more smooth and polished. An experienced farmer (whose description the reader, whose heart is peculiarly set on this wine; adding, that he has frequently observed, when the morning has been cold, the sensitive leader of a tender bush

fully commenced on the return of good weather in March when the hills are spread out, it is better to give opportunity to the wind to draw the stocks. The earth being then saved from the principal roots by an iron instrument called *picker* the remains of the former year's crop is cut off together with the shoots which were not allowed to stretch downwards to the poles in the former season, and also any young suckers that may have sprung up about the edges of the hills, so that nothing is allowed to remain that is likely to injure the principal crop, or impede their shooting out strong vigorous ones at the proper season. After the roots have been properly cleared and ground, the hills are again fenced, with an addition, if not every year at least every second or third year of a proper quantity of compost manure, that had been previously laid in some heaps on the hop-ground, in the course of the winter or in the early part of spring. At this season such acts as procured as may be wanted for the manure or for new plantations.

6030. *In regard to the size of the poles, however, it is well known, have their respective choice or approbation with respect to the thickness of their support, explaining all greater readiness, and that is not exactly small, than one which is thick, is the bottom. The ordinary circumference of poles at the thickest end, may be set out, as from six to nine inches improving to the size of walking cane at the top, and the length from fifteen to twenty feet or upwards. Different grounds require different lengths of poles. In the best grounds, in the neighbourhood of Maidstone, the poles of seven feet stand, in general, from fourteen to sixteen feet above the hill, and have from eighteen inches to two feet beneath the surface. But on weaker lands, poles are not seen to rise more than ten to twelve feet high. Hence the variety of ground is convenient, as the poles, by decaying at the roots, grow shorter and, in course of years, get too short for strong uses, on rich land they are in this case sold, and transferred to less productive lands, and vines of humbler growth.*

6031. *New poles have sometimes the bark shaved off* under an art that is given them from the worm; while some men are of opinion that this is a waste in the land, which is portable to the young vines; and although in two or three years the bark drops off the surface of the wood bare, that is, a light degree of softness. Whether, hard, smooth, polished pole is unduly to the hop or not, to peel the pole would evidently be improper as preventing their decay.

6032. *Short April poles are usually planted in land without other support;* but the tall heavy poles require something to keep the top steady. This is obtained by using together three poles of equal length two or three feet from the top, and setting them up in the form of what is called *triangles* in the way the leading timber on wheat-carriages. The top of the pole is sharpened, being dropped in between the points of the triangle, receive the required stay; and a third is placed in a convenient situation below to work on. This sort of work, whether on new or on old poles, is sometimes done when they are stacked or set up in place, sometimes immediately before they are planted. In planting poles that have been so set up the procedure is such that the pole which stood in the first instance struck off and a fresh pole given to the second part, if the bottom pole remains firm, it is sharpened for another season.

6033. *Wires of copper or iron have been tried as substitutes for wooden poles in the neighbourhood of France;* but, having seen a plantation thus treated in this way we do not think it very improvable. The vines are stretched horizontally in the direction of the row of poles, the first wire five feet from the ground, the second one foot above it, and so on, till the height of fifteen feet. The plants are led to the lowest wire by short sides, and left to twist up or along the others in pleasure.

6034. *Tying the shoots or vines to the poles* is the last operation in the after or summer culture of the hop. This requires the labour of a number of persons, generally women, who tie them in several different places with withered rushes, but so loosely as not to prevent the vines from advancing in their progress towards the top of the poles. When the vines have got out of reach from the ground, proper persons go round, with standing ladders, and tie all such as appear inclined to stray.

6035. *The season for this operation varies from the middle of May to the end of June, and one important part of the operation consists in selecting the shoots.* The forwardmost vine should always be selected, as it is well known that the branches arising from these early shoots will produce little, if any, fruit. The second shoot, where the tiller can not develop with plenty, and where the ground is not of a nature to need such very humant rate, city with many be tied up but in the land is apt to push forward a great redundancy of shoots, where the vine is always strong and vigorous, and where the future in the crop chiefly arises from this source, the greatest production is necessary at the season for tying to make choice of proper vine, especially in years which may be supposed to be "landed with" blast, and as those who are entirely well and has prevailed throughout the month of March, whence one may fairly conclude that the same weather will happen during the course of the month of May which never fails to bring the long winged fly. In such season it would be well worth while to eradicate all the vine which first appears, and to cut to the root, so as to prevent their taking off the last week in May. The kind was taken from the observations made in such backward years on the poor and thin lands where the vine is sure to be backward, and seldom becomes fit for the eye till towards the latter end of May when that on the forward ground will have advanced twenty in the tops of the poles, and to an attentive observer seems to promise fair for a crop. Whereas, to those who have been conversant in these matters, the lower of the crop, though the vine at that time be green and flourishing may be easily foreseen what on the poorer soils there is possibly saving crop even in years when the blast is most prevalent. These considerations have suggested the postponing of the growth of the vine in the manner there mentioned, which seems comfortable to reason and experience.

6036. *Taking the crop is a most important operation in the hop economy*

6037. *Hops are known to be ready for pulling* when they acquire a strong scent, and the seeds become firm and of a brown colour which, in ordinary seasons, happens in the first or second week of September. When the pulling season arrives, the utmost assiduity is requisite on the part of the planter in order that the different operations may be carried on with regularity and despatch, as the first neglect, in any department of the business, proves in a great degree ruinous to the most abundant crop, especially in precarious seasons. Gales of wind at that season, by breaking the lateral branches, and bruising the hops, prove nearly as injurious as a long continuance of rainy weather which never fails to spoil the colour of the crop, and thereby render it less saleable.

6038. *As preparations for pulling the hops frames of wood, in another preparation in the day of the hop, the poles are to be selected, are placed in that part of the field which is the most exposed to the influence of the sun, is secured ready. These frames, which are called *cries* or *cries*, are very simple in the construction, being only four pieces of boards nailed to four posts or legs, and when finished, are about seven or eight feet long, three feet broad, and about the same height. A man always attends the poles, whose business it is to cut over the men near the ground and to lay the poles on the frames to be pulled. Commonly two, but seldom more than three, poles are laid on at a time. By seven or eight p men, women, girls, and boys, are employed at the same time, three or four being in the frame, and the others round the man who sorts the poles, are called *sets*. The hops, after being carefully separated from the leaves and lichen, or stalks, are dropped by the rollers into large clogs, being all round within side the frame on either side. When the hop is full, the hops are emptied into large sacks, which are carried home, and the hops laid on fire to be dried. It is a strange dose as soon as possible after they are packed as they are apt to sustain considerable damage both in colour and flavour, if allowed to remain long in sacks in the green state in which they are pulled. I very warm weather and when they are pulled in moist state they will often heat in six or six hours. For this reason the kilns are kept constant, i.e. with a hot fire all day from the commencement to the conclusion of the hop picking season.*

6039. *The number of hands is a matter of production, in the picking season, that the oaks or kilns may never be unoccupied with hops, and if it is found that the hops rise faster than could have been expected, and that there are more gathered in a day than can be conveniently dried, all some of the worst pickers may be discharged, it being very prejudicial for the poor hops to continue long in the sacks before they are put on the clog, in they will in a few hours begin to heat and acquire an unsightly colour which will not be taken off in the drying, especially if the season be very moist. Though, in wet hopping, it is no easy matter to prevent the kilns from being over-run, supposing that there are pickers enough to supply them of the material had been dry. However, in cold times the hops require to be considerably while longer on the kiln in order that the superabundant ones may be dried. It is therefore expedient in the case that each man should be paid not number of green pickers or poles. The number of bushels in a pole ought never to exceed eleven, but when the hops are dry, or (if it is constant together some time before they go on the kiln, the better way is to get only eight bushels in each pole, or pole.*

6040. *Remembering that, different hop pickers, when the crop is tolerably abundant, will pick from six to ten bushels in a day, which when dry will weigh about one hundred weight, and that it is common to let six pickers of hops ground in the wheel. The price is an extremely variable depend on less on the goodness of the crop than on the abundance or scarcity of labourers. The greatest price for hops cultivated in England is paid by people who make practice of coming annually from the remote part of Wales for that purpose.*

6041. *The operation of drying hops is not materially different from that of drying malt and the kilns, or oasts, are of the same construction*

6042. *The hops are spread on a hair cloth, and from eight to ten, sometimes twelve, inches deep, according to the dryness or wetness of the season and the ripeness of the hops.* A thorough knowledge of the best method of drying hops can only be acquired by long practice. The general rules are to begin with a slow fire, and to increase it gradually, till, by the heat on the kiln and the warmth of the hops, it is known to have arrived at a proper height. An even steady fire is then continued for eight or ten hours according to the state or circumstances of the hops, by which time the ends of the hop-stalks become quite shrivelled and dry, which is the chief sign by which to ascertain that the hops are properly and sufficiently dried. They are then taken off the kiln, and laid in a large room or loft till they become quite cool. They are now in condition to be put into bags, which is the last operation the planter has to perform previously to sending his crop to market.

6043. *When hops are dried on a cockle-oast, sea-coal is the usual fuel, and a chaldron is generally reckoned the proper allowance to a load of hops.* On the hair kilns, charcoal is commonly used for this purpose. Fifty sacks of charcoal are termed a load which usually sells for about fifty shillings. The price for burning is three shillings per load or twelve shillings for each cord of wood. The process of drying having been completed, the hops are to be taken off the kiln and she off into an adjoining chamber called the storage-room and in this place they are continually to be laid as they are taken off the kiln till it may be thought convenient to put them into bags, which is rarely done till they have been some time in the heap. For the hops when first taken off the kiln being very dry, would (if put into the bags at that time) heat to rot, and not draw so good a sample as when they have lain some time in the heap whereby they acquire a considerable portion of toughness, and an increase of weight.

6044. *The bagging of hops is thus performed* —

6045. *In the floor of the room, where the hops are laid to cool there is a round hole or trap, equal in size to the mouth of a hop bag. After tying a handful of hops in each of the lower corners of a large bag, which serve afterwards for handles, the mouth of the bag is fixed securely to a strong hoop, which is made to rest on the edges of the hole or trap, and the bag itself being then dropped through the trap, the packer goes into it, when a person who attends for the purpose puts in the hops in small quantities, in order to give the packer an opportunity of packing and tramping them as hard as possible. When the bag is filled, and the hops tramped in so hard as that it will hold no more, it is drawn up unloaded from the hop, and the end sewed up, other two handles having been previously formed in the corners in the manner mentioned above. The brightest and finest coloured hops are put into pockets or fine bagging and the brown into coarse or heavy bagging. The former are chiefly used for brewing fine ales, and the latter by the porter brewers. But it is to be observed that where hops are intended to be kept for any length of time, it is most proper to put them into coarse cloth. The proper length of a bag is two ells and a quarter and of a pocket nearly the same, being one ell in width. The former if the hops are good in quality will serve, and the latter will weigh about two hundred and a half, and the latter if of the Canterbury packing, about one hundred and a half. If the weight either exceeds or falls much*

short of this medium, it induces a surmise, that the hops are either in themselves of an inferior quality or have been injudiciously manufactured in some respect or other.

6046. *Fallaise's apparatus for picking and preserving hops* is an hexagonal case of wood, eighteen feet long and two feet in diameter with a piston or rammer, to be worked by a screw or other means so as to compress the hops more closely than has hitherto been done. When the case is full a lid is fastened down by iron plates and nails, and any crack or joint that may appear is filled with cement, so as to exclude the air. With this precaution, Mr. Fallaise states, hops may be kept perfectly good for half a century (*Arden's Journal*, vol. vii. p. 12.)

6047. *The stripping and stacking of the poles* succeed to the operation of picking. It is of some consequence that this business be executed as soon as possible after the crop is removed not only because the poles are, when set up in stacks, much safer from thieves, but because they are far less damaged by the weather than when dispersed about the ground with the vines on them. The usual price for stripping and stacking is five shillings per acre. At this time such poles as may be deemed unfit for further service should be flung by that the planter may have an early knowledge of the number of new poles which will be wanted and thus the business of bringing on the poles may be completed in the winter time when the horses are not required about other labour and these new poles may be drawn from the wood on the ground, and adjusted to the separate stacks, as the state of the different parts of the ground may require, and the whole business finished before the poling season whereas, when this method of flinging out the old poles is neglected at the stacking the planter being ignorant of the number of new poles that will be required for the ensuing year, often finds at the poling season that he has not laid in a sufficient stock.

6048. *In performing the operation of stacking* the poles are set up in somewhat conical piles, or congeries of from two hundred to five hundred each. The method of proceeding is thus — Three stout poles of equal length are bound together, a few feet from their tops and their feet spread out, as those already mentioned for pointing the poles. These serve as a stay to the embryo pile the poles being dropped in on each side, between the points of the first three cautiously keeping an equal weight on every side for on this to balance the stability of the stack depends. The degree of inclination or slope, and the diameter of the base of the pile, vary with the length and the number of poles set up together. A stack of three or four hundred of the long poles of the environs of Maidstone occupy a circle of near twenty feet in diameter. It is observable however that the feet of the poles do not form one entire ring but are collected in bundles or distinct divisions generally from three to six or eight in number each fasciculus being bound tightly together a few feet from the ground, with a large rough rope made of twisted vines, to prevent the wind from tearing away the poles. The openings between the divisions give passage to violent blasts, and tend to prevent the piles from being thrown down in a body a circumstance which does not often take place in screened grounds, but, on the high exposure of Cox Heath, where great quantities of new poles brought out of the Weald are piled for sale among the Maidstone planters, it is not uncommon for the piles to be blown down, and to crush in them all the sheep or other anim. in that way! a precaution which is wanted, for the wantonness of the devil.

6049. *The operation of stripping* is generally performed by women, being nothing more than tearing off the bind or vines. Many people burn it on the ground others suffer it to be carried off by their work men for firing and there are some who tie it up into small bundles which they bring home and form into a stack, to answer the purpose of having in heating their ovens or coppers.

6050. *The produce of the hop crop* is liable to very considerable variation, according to soil and season, from two or three to so much as twenty hundred-weight but from nine to ten, on middling soils, in tolerable seasons, are considered as average crops and twelve or fourteen as good ones. Bannister asserts that sixty bushels of fresh-gathered hops, if fully ripe, and not injured by the fly or other accident, will, when dried and bagged, produce a hundred-weight. Where the hops are much eaten by the flea, a disaster which often befalls them the sample is not only reduced in value, but the weight diminished so that, when this misfortune occurs, the planter experiences a two-fold loss.

6051. *To judge of the quality of hops*, as the chief virtue resides in the yellow powder contained in them, which is termed the condition, and is of an unctuous and clammy nature, the more or less clammy the sample appears to be the value will be increased or diminished in the opinion of the buyer. To this may be added the colour which it is of very material consequence for the planter to preserve as bright as possible, since the purchaser will always insist much on this article, though perhaps, the brightest-coloured hops are not always the strongest flavoured.

6052. *The duration of the hop plantation* on good soil may be from fifteen to thirty years but in general they begin to decline about the tenth year. Some advise that the plantation should then be destroyed and a fresh one made elsewhere others consider it the best plan to break up and plant a portion of new ground every two years letting an equal quantity of the old be destroyed, as in this way a regular succession of good plantation will be kept up at a trifling charge.

6053. *The expense of forming new hop plantations* is in general very great being estimated, in many districts, at more not less than seventy to a hundred pounds the acre. The produce is very uncertain, often very considerable; but in some seasons nothing, after all the labour of culture, except picking, has been incurred. Where the lands are of proper sort for them and there are hop-poles on the farm, and the farmer has a sufficient capital, it is probably a sort of husbandry that may be had recourse to with advantage but under the contrary circumstances, hops will seldom answer. In growing them in connection with a farm regard should be had to the extent that can be manured without detriment to the other tillage lands. On the whole, the hop is an expensive and precarious crop, the culture of which should be well considered before it is entered upon.

6054. *The use of the hop in brewing* is to prevent the beer from becoming sour

6055. In domestic economy the young shoots are eaten early in the spring as asparagus, and are sold under the name of hop-seeds. They are said to be diuretic and taken in an infusion, to be good against the scurvy. The herb will dye wool yellow. From the stalks a strong cloth is made in Sweden; for this purpose they must be gathered in autumn, soaked in water all winter and in March after being dried in a stove they are dressed like flax. They require a longer time to rot than flax, and, if not completely macerated, the woody part will not separate, nor the cloth prove white or fine. Hence a farmer who has a hop plantation need neither grow asparagus nor flax, and may when the flowers fall from disease, separate the fibre from the vine, and employ the poor or machinery in spinning and weaving it. A decoction of the roots of hops is considered as good a sudorific as saraparilla, and the mud of the flowers is found to be soporific. A pillow filled with hops was prescribed for the use of George III. in his illness of 1767.

6056. *The hop is peculiarly liable to diseases.* There is scarcely any sort of plant cultivated as a field-crop that is more liable to become diseased than the hop. It is apt, in the very early stage of its growth, to be devoured as it rises above the surface of the ground, by the ravages of an insect of the flea kind. At a more advanced stage, it is subject to the still more injurious effects of the green or long winged fly red spider and other moth the first, by the depositing of their ova, afford the means of producing lice in great abundance, by which the plants are often very greatly if not wholly destroyed, and the larvae of the last prey upon the roots, and thus render the plants weak and subject to disease. The honey-dew is another disease to which the hop is exposed about the same time, and by which it is often much injured. The mould occurs in general at a somewhat later period, and is equally injurious. Hop-crops are also exposed to other injuries, as the blight and fire blast but which take place at different times, though mostly towards the latter periods of the growth of the plants.

6057. *The Flea,* which is said to be an insect of the same kind as that which is so prejudicial to the young turnip is observed to make the greatest havoc in seasons when the nights are cold and frosty and the days hot and inclined to be dry, eating off the sweet tender tops of the young plants, which, though not wholly destroyed, shoot forth afterwards in a far less vigorous manner and of course become more exposed to diseases. It has been found to commit its depredations most frequently on the plants in grounds that have been sown the same year on which account it has been suggested that the manure employed for the purpose of covering the hills should be previously well mixed and incorporated, as directed above (6019) and that it should be applied either over the whole of the land or only the hills, as soon as possible after the plants have been cut over but the former practice is probably the best. It makes its greatest depredations in the more early cold, spring months, as the latter end of April and beginning of the succeeding month disappearing as the season becomes more mild and warm. In these cases, the principal remedy is that of having the land in a sufficient state of fertility to enable the young plants to shoot up with such vigour and rapidity as to become quickly incapable of being fed upon and devoured by the insect. The frequent stirring of the mould about the roots of the plants with the hoe may be of utility in the same view.

6058. *The green or long-winged fly* is highly destructive to the young leaves of the plants, and mostly makes its appearance about the latter end of May and in the two succeeding months being ignorantly supposed to be produced by the prevalence of north-easterly winds about that period. Under such a state of the wind they are said to scarcely ever fail of covering the leaves and by dropping their ova, of producing abundance of lice which often much injure the crops as when they have once obtained complete possession of the plants, they seldom or never leave them before they have wholly destroyed them. Insects of this sort generally attack the forwardest and most luxuriant hop-vines. Their removal chiefly depends upon the wind changing more to the south and the setting in of more mild warm, and temperate weather.

6059. *The other moth,* by depositing its eggs upon the roots of the plants, renders them liable to be attacked by the larvae, and the healthy growth of the hops is thereby greatly impaired, the crops being of course much injured in their produce. Stirring the earth well about the roots of the plants may probably sometimes be serviceable in cases of this kind.

6060. *The honey dew* mostly occurs after the crops have been attacked by some of these kinds of insects, and when the weather is close, moist, and foggy. In these cases a sweet clammy substance which has the taste of honey, is produced upon the leaves of the plants, and they have at first a shining appearance, but soon afterwards become black. It is a disease that mostly happens in the more forward crops and the chief dependence of the planter for its removal, according to Bannister is that of heavy thunder showers taking place; as by this means, when the destruction of the hops has not proceeded too far they are often much restored, the insects that devour the leaves and vines being greatly destroyed, the growth of fresh shoots promoted, and a favourable bloom brought on the plants.

6061. *The fire, mould, or mildew* is a disease to which the crop is exposed at a later period of its growth and which chiefly attacks the part where the hop is attached to the stem. It is said that its production is greatly promoted by moist damp weather and a low situation those crops that grow on low close, rich grounds being most liable to be attacked by it and it is found to soon spread itself over the whole crop, after it has once seized upon any part of it. The nature of this vegetable disease has not been yet sufficiently investigated. It has been suggested by Darwin and Willdenow to be a plant of the fungus kind, capable of growing without light or change of air attaching itself to plants already in a morbid condition, and by its roots penetrating their vessels and on this supposition, the best remedy is believed to be thinning the plants, in order to afford a more free circulation of air and admit the light more extensively by which the vigour of the hop-plants may be restored and the disease be of course removed. In this view it is probable, by planting the hills more thinly and making them at greater distances from each other the disease might in some measure be prevented from taking place. (See 1894.)

6062. *Diseases termed blights* are frequently met with in hop-crops, at different periods of the growth of the plants, but mostly in the more early stages of their rising from the hills, while the nights are cold and frosty in the spring months, and the days have much sun and heat by which the living powers of the plants are greatly exhausted in the day time by the stimulus of heat, and of course much injured or wholly destroyed in the nights, from being exposed to a freezing air which is incapable of exciting the actions necessary for the preservation of vegetable life. As the presence of this disease is supposed to be greatly connected with the prevalence of winds from the northern or easterly quarters, there is often a sea produced of a similar kind to that which attacks the shoots in their early growth. (6057) It is highly injurious, by preventing upon the nutriment of the blossoms, and thereby diminishing their weight and changing them to a brown colour; which is very prejudicial in their sale at the market.

6063. *The fire-blast* is a disease the hop-crops are exposed to in the later periods of their growth, and is generally supposed to proceed from the particular state of the air or weather. Others consider this disease as nothing more than the result of the attacks of the red spider. It has been conjectured to be the effect of lightning, as it takes place, for the most part, at those seasons when lightning is the most prevalent,

and in a very sudden manner: and besides the most forward and luxuriant vines are the most subject to be affected. It has been suggested, that in exposures where the crops are particularly liable to injury, it may be advisable to plant thinner, to keep back the growth of the plants as much as possible, by excluding all the most forward shoots, and to employ a less proportion of the earthy support in their culture.

6064. As respect to the duty on hops, it is best for the planter to have the acts before him. But every grower of hops in Britain is legally obliged to give notice to the excise, on or before the first day of September of the number of acres he has in cultivation, the situation and number of his oasts, and the place or places of bagging, which, with the store-rooms, or warehouses, in which the packages are intended to be lodged, are entered by the revenue officer. No hops can be removed from the rooms thus entered, before they have been weighed and marked by a revenue officer who marks, or ought to mark, not only the weight, but the name and residence of the grower, upon each package.

#### SUMMARY 2. Culture of the Coriander and Caraway. (Fig. 804. a, b.)

6065. The coriander (*Coriandrum sativum* L. fig. 804 a) is a small-rooted annual, with branching stems rising from one foot to one foot and a half in height. It is a native of the south of Europe, and appears to be naturalized in some parts of Essex where it has been long cultivated. It flowers in June and July, and the seeds ripen in July and August.

6066 The culture and management of coriander consist in sowing it on a light rich soil in September, with seeds ripened the same year. Twenty pounds of seed will sow an acre. When the plants come up, thin them to six or eight inches distance every way and, next spring, stir the soil with a pronged hoe. In August the seed will be ripe, and if great care be not used the largest and best part of it will be lost. To prevent this, women and children are employed to cut plant by plant, and to put them immediately into cloths, in which they are carried to some convenient part of the field, and there thrashed upon a sail-cloth. A few strokes of the flail get the seeds clean out, and the threshers are ready for another bundle in a few minutes. In Essex it is sometimes cultivated with caraway and tansy. (See Caraway.)

6067 The produce of coriander is from ten to fourteen cwt. on an acre. It is used by the distillers for flavouring spirits, by the confectioners for encrusting with sugar and by the druggists for various purposes for all of which it is said to have a ready sale.

6068. The caraway (*Cuminum Cuminum*, b) is a biennial plant with a taper root, like a parsnep, but much smaller running deep into the ground. The stems rise from eighteen inches to two feet, with spreading branches and finely cut deep green leaves. It is a native of England, in rich meadows in Lincolnshire and other places, and has been long cultivated in Essex. It flowers in May and June, and the seeds ripen in autumn.

6069 The culture and management are the same as those of coriander. In all probability both plants would answer if sown like clover among a crop of corn and hoed and thinned when the crop was removed, and again in the following spring. The method of culture in Essex is, about the beginning of March to plough some old pasture land if it has been pasture for a century the better and the soil should be a very strong clayey loam. Twelve pounds of caraway seed are sowed with ten pounds of coriander and twelve pounds of tansy seed this is sufficient for one acre and is sowed directly after the plough harrowing the land well. When the plants appear of sufficient strength to bear the hoe, which will not be until about ten weeks after sowing, it must not be omitted and at the close of the summer the crop will require three hoeings, besides one at Michaelmas. The coriander being annual will be fit to cut about the beginning of July it is left in the field after cutting, and thrashed on a cloth in the same manner as rye-seed. About April following the caraway and tansy will want a good hoeing done deep and well, and another about the beginning of June. The caraway will be fit to cut in the beginning of July, and must be thrashed in the same manner as the coriander. This compound crop is mostly sown on land so strong as to require being a little exhausted to make it fit for corn. Caraway and coriander are often sown with out tansy the latter being a troublesome and uncertain crop, and the produce of caraway much greater without it.

6070 The produce of caraway on the very rich old leys in the hundreds or low lands of Essex has often amounted to twenty cwt. an acre. There is always a demand for the seed in the London market.

6071 The uses of the caraway are the same as those of coriander and its oil and other preparations are more used in medicine. Dr Anderson says, both the roots and tops may be given to cattle in spring.

#### SUMMARY 3. Plants which may be substituted for Brewery and Distillery Plants.

6072. As substitutes for hops, we may mention the common box (*Buxus sempervirens*), the leaves and twigs of which are said to be extensively used in all the beer brewed in Paris. The marsh trefoil (*Menyanthes trifoliata*) is much employed in Germany, and on the Continent generally; and, it is said was formerly used in this country. One ounce of the dried leaves is considered equivalent to half a pound of hops. The plant is of easy culture in moist soil all the plants of the same natural order, *Gentiana*, and especially the different species of *Gentiana*, might be used in the same manner, more particularly the *G. litsea*, *ribra*, and *purpurea*. In Switzerland, a spirit is distilled from the roots of *G. litsea*. The dried roots of *Gleum urbicum*, common in hedges, are sliced,

enclosed in a thin linen bag, and suspended in the beer cask, by the brewers of Germany to prevent, it is said, the beer from turning sour, and to give it the odour of cloves. (*Gard. Mag.* vol. vi p. 148.) In Sweden, Norway and the north of Scotland, the heath (*Erica L.*) and common broom were, and still are, occasionally used as substitutes for the hop. In some parts of France and Germany nothing else is used but broom tops. In Guernsey the *Tedcrum Scorodonia* is used, and found to answer perfectly. In England, the different species of mugwort and wormwood have been used for that purpose; and the foreign bitter quassia, a tree of Guiana, is still used by the porter brewers. Whoever has good malt, therefore, or roots, or sugar and understands how to make them into beer need be at no loss for bitters to make it keep.

6073. *Carminative seeds* equal in strength to those of the caraway and coriander, are furnished by a very considerable number of native or hardy plants, and of flavour to which the drinkers of cordials and liqueurs are attached. Such are the fennels (*Feniculum*) cultivated in Germany, parsley, myrrh, angelica, celery, carrot, parsnep, cow parsnep, and many other umbelliferous plants, avoiding, however the hemlock, fool's parsley, athusa, and some others which are poisonous. In Dantzic, where perhaps more seeds are used for flavouring spirits than any where else, several of the above and other plants are employed. Kummel, their favourite flavour is that of the cumen (*Cuminum Cuminum*) an annual plant, a native of Egypt, and cultivated in the south of Europe but too tender for field culture in this country. But caraway or fennel seeds are very generally mixed with cumin, or even substituted for it in distilling kummel-wasser.

### SECT. III Oil Plants.

6074. In Britain there are few plants grown solely for the production of oil though oil is expressed from the seeds of several plants, grown for other purposes, as the flax, hemp, &c. Our chief oil plant is the rape.

6075. Rape is the *Brassica Napus L.* *Navette*, Fr. *Rubensamen*, Ger. *Raps silvestris*, Ital. and *Nabe silvestre*, Span. It is a biennial plant of the turnip kind, but with a caulescent or woody fusiform root scarcely fit to be eaten. Von Thier considers the French and Flemish colza (*Kohleaat* Ger.) a different plant from our rape colza is more of the cabbage kind, and distinguished by its cylindrical root, cut leaves, and greater hardness. Decandolle seems to be of the same opinion.

6076. *Brassica campestris oleifera*, according to these writers is the colsat or colza, or rape of the Continent, the most valuable plant to cultivate for oil its produce being to that of the *Brassica Napus*, or British colsat or rape as 95 to 700. It is distinguished from the *B. Napus* by the hispidity of its leaves. It would be desirable for agriculture, Decandolle observes, that, in all countries, cultivators would examine whether the plant they rear is the *B. campestris oleifera* or the *B. Napus oleifera*, which can easily be ascertained by observing whether the young plant is rough or smooth. If hispid, it is the *B. campestris* if glabrous, the *B. Napus*. Experiments made by Gaujeu show the produce of the first compared with that of the second, to be as 256 to 700. (*Essai. Trans.* v. 52.)

6077. For its leaves as food for sheep and its seed for the oil-manufacturer, rape or colseeds, has been cultivated from time immemorial. It is considered a native, flowers in May, and ripens its seeds in July. It may be sown broad-cast, or in rows, like the common turnip, or it may be transplanted like the Swedish turnip. The culture of rape for seed has been much objected to by some, on account of its supposed great exhaustion of the land, but where the soil and preparation are suitable, the after-culture properly attended to, and the straw and offal, instead of being burnt, as is the common practice, converted to the purposes of feeding and littering cattle, it may, in many instances, be the most proper and advantageous crop that can be employed by the farmer.

6078. The *Collage in Northumberland* used to cultivate rape on thin clay, as a preparation for wheat of which they had valuable crops afterwards. The land in the early part of the season was prepared as for fallow and the rape sown in June or July and eaten off by sheep in September or October after which the soil was once ploughed for wheat. The rape may also be sown among a crop of drilled winter beans in May.

6079. The soils best suited for rape are the deep rich, dry and kindly sorts but, with plenty of manure and deep ploughing, it may be grown in others.

6080. Young rape, that upon fine and peat soils and bogs, and black peaty low grounds it thrives greatly and especially on pared and burnt land, which is best suited to it but it may be grown with perfect success on stony marshy, and other coarse waste lands, that have been long under grass, when broken up and properly prepared. As a first crop on such descriptions of land it is often the best that can be employed. The author of *The New Farmer's Calendar* thinks that this plant is not perhaps worth attention on any but rich and deep soils; for instance, those luxuriant silts that are found by the sea-side, fen, or newly broken up grounds, where vast crops of it may be raised.

6081. The preparation of old grass lands if not pared and burned, need be nothing more than a deep ploughing and sufficient harrowing to bring the surface to a fine mould and this operation should not be commenced in winter because the grub and wire-worm would have time to rise to the surface; but in February or March immediately before sowing, or in July, or after the hay crop is removed, if the sowing is deferred till that season. When sown on old dilapidated lands, the preparation is pretty much the same as that usually given for the common turnip the land being ploughed over four or five times, according to its condition as a fine state of pulverisation or tilth is requisite for the perfect growth of the crop. In this view the first ploughing is mostly given in the autumn that the soil may be exposed to the influence of the atmosphere till the early part of the spring when it should be again turned over twice, at proper intervals of time and towards the beginning and middle of June one or two additional ploughings should be performed upon it, in order that it may be in a fine mellow condition for the reception of the seed.

6082. In a rotation of crops, the place which rape occupies is commonly between two of the culmiferous kind. On rich soils it may be succeeded to the greatest advantage by wheat, as it is found to be an excellent preparation for that sort of grain and by its being taken off early, there is sufficient time allowed for getting the land in order for sowing wheat.

6083. The season for sowing rape is the same as that for the common turnip, and the manner, whether in broad-cast or rows, the same.

6084. The row method on the flat surface seems the best for newly broken up lands; and the rows on ridges, with or without manure, the best for lands that have been under the plough. Where the object is the keep of sheep in autumn or winter by eating it down, the broad-cast method and thick sowing are evidently the best, and are generally resorted to in Lancashire and the fenny districts. The quantity of seed when sown thick may be a peck an acre but when drilled or sown thin, two or three pounds will suffice. The seed should be fresh, black, and plump. Vacancies may always be filled up by transplanting.

6085. The season of transplanting begins as soon after the corn harvest as possible, being generally performed on the stubble of some description of corn crop.

6086. One deep ploughing and a degree of harrowing sufficient to pulverise the surface, are given, and the plants may be dibbled in in rows a foot apart, and six inches in the row or narrower according to the lateness of the season of planting, and the quality of the soil. For it must be considered that plants transplanted so late as September or October will be far from being so strong in the succeeding spring as those sown in June and left where they are to run. The seed bed from which the plants are obtained should have been sown in the June or July preceding the transplanting season, and may be merely a ridge or two in the same or in an adjacent field. We have already noticed (604) the Flemish mode of transplanting, by laying the plants in the furrow in the course of ploughing but as the plants cannot be properly firmed at the lower part of the root, we cannot recommend it.

6087. The after-culture of rape is the same as that of the turnip, and consists in hoeing and thinning.

6088. The plants on the poorer soils may be left at six or eight inches apart or narrower, but on the rich they may be thinned to twelve or fifteen inches with advantage to the seed. Few are likely to grow the plant on ridges with manure; but, if this were done, the same distance as for turnips will ensure a better crop of seed than if the plants were closer together. In close crops the seed is only found on the remnants of the plants in wide ones or rich soils, it also covers their sides. When rape seed is grown purposely for sheep keep, no hoeing, thinning, or weeding, are necessary. Rape grown for seed will not be much injured by a very slight cropping from sheep early in the autumn but considerably so by being eaten down in winter or in the succeeding spring. The seed begins to ripen in the last week in June, and must then be protected as much as possible from birds.

6089. In harvesting rape great care is requisite not to lose the seed by shaking, chaffing, or exposure to high winds or rains.

6090. It is reaped with the hook and the principal point is to make good use of fine weather for as it must be threshed as fast as reaped or at least without being housed or stacked like other crops, it requires a greater number of hands in proportion to the land, than any other plant. The reaping is very delicate work. For if the men are not careful, they will shed much of the seed. Moving it to the threshing floor is another work requiring attention. One way is to make little waggons on four wheels with poles, and cloths strained over them; the diameter of the wheels being about two feet, and the cloth body five feet wide, six long, and two deep: these are drawn by one horse, and the whole expense is not more than 3s. or 4s. In large farms, several of these may be seen at work at a time in one field. The rape is filled from the ground gently dropped at once into these machines without any loss, and carried to the thrashers, who keep hard at work being supplied from the waggons as fast as they come, by one set of men, and their straw moved off the floor by another set. Many hands of all sorts being employed, a great breadth of land is finished in a day. Some use sledges prepared in the same way. All is liable to be stopped by rain and the crop much damaged. It is, therefore of very great consequence to employ as many people as possible, men, women, and boys, to make the greatest use of fine weather. The seed is likewise sometimes cleaned as the field, and put into sacks for the market. But when large quantities of seed are brought quickly together as they are liable to heat and become mouldy it may be a better method to spread them out thinly over a barn, granary or other floor and turn them as often as may be necessary.

6091. The produce where the plant succeeds well, and the season is favourable for securing the seed, amounts to forty or fifty bushels or more on the acre. Marshal thinks, indeed, that on the whole it may be considered as one of the most profitable crops in husbandry. There have been, says he, instances, on cold, unproductive, old pasture lands, in which the produce of the rape crop has been equal to the purchase value of the land. The seed is sold by the last of ten quarters, for the purpose of having oil expressed from it in mills constructed for that purpose. The price, like that of all crops of uncertain and irregular demand, is continually varying.

6092. The uses to which the rape is applied are the following —

6093. The use of the seed for crushing for oil is well known; it is also employed as food for tame birds, and sometimes it is sown by gardeners, in the same way as mustard and cress, for early salading.

6094. The rape-cake and rape-dust, the former adhering masses of seed husks, after the oil has been expressed, are the latter being dry husks, are used as a top-dressing for crops of different kinds. They are reduced to powder by a walk mill or other grinding machine and sometimes sown broad-cast over young clovers, wheats, &c., and at other times drilled along with turnip seed. Four hundred weight of powder sown with turnip seed will go over one acre in drills, but three times the quantity is required for an acre sown broad-cast. Experience has proved, that the success of this manure depends in a great measure on the following season. If rain happens to fall soon after the rape-dust is applied, the crop is generally abundant; but if no rain falls for a considerable period the effects of this manure are little discernible, either on the immediate crop or on those which succeed it. There are turnip drills contrived so as to deposit the manure along with the seed.

6095. The use of the husks to cattle in winter is very considerable. The stover (pods and points broken off in threshing) is as acceptable as hay and the tops are eaten nearly as greedily as cut straw and are at least better than wheat straw. When well got, the smaller stalks will be eaten up clean. The oil makes excellent litter for the farm-yard, and is useful for the bottoms of mares, cows, &c. The husks of this plant is frequently burned; and, in some places, the ashes, which are equal to potash, are sold; by which means, if no manure is substituted, the soil must be greatly deteriorated. It is a custom in Lancashire,

sometimes to lay lands down with clover, under which the grass seeds are found to grow well. But this sort of crop, as already observed, is most suited to freshly broken-up or burned lands, or to succeed early peas, or such other green crops as are mowed for feeding cattle.

6088. The leaves as a green food for sheep are scarcely surpassed by any other vegetable, in nutritious properties, and in being agreeable to the taste of the animals; but in quantity of produce, it is inferior to both turnips and cabbages. The crops are fed off occasionally from the beginning of November to the middle of April, being found of great value, in the first period, for fattening dry ewes, and all sorts of old sheep; and in the latter for supporting ewes and lambs. The sheep are folded upon them in the manner practised for turnips in which way they are found to pay from 50s. to 60s. the acre that quantity being sufficient for the support of ten sheep, for ten or twelve weeks, or longer, according to circumstances. Rye has been found, by experience, to be superior to turnips in fattening sheep, and in some cases, even to be apt to destroy them by its fattening quality. In *The Corrected Report of Lincolnsire* it is likewise observed, that rape grown on fresh land has the stem as brittle as glass, and is superior to every other kind of food in fattening sheep; while that produced on old tillage land has the stem tough and wiry and containing comparatively little nourishment.

6097. *The Sésamum orientale* (*Sesame*, Fr. *Sesamo*, Ital.), *Bignoniaceae*, is cultivated in Italy for its seeds, which are eaten roasted like those of maize, boiled like those of the millet, made into a coarse flour like those of the beech or buck wheat, but principally bruised for an oil used as a substitute for butter.

6098. Among other plants which may be cultivated by the British farmer as oil plants, may be mentioned all the species of the *Brassicæ* family, the *Sinapis* or mustard family, and the *Râphanus* or radish family with many others of the natural order of *Cruciferae*. The seeds of these plants, when they remain too long on the seedsmen's hands for growing, are sold either for crushing for oil or grinding with mustard seed. This includes a good deal of wild charlock and wild mustard seed, which is separated in the process of cleaning grain by the farmers among whose corn these plants abound, and sold to the seed agents who dispose of it to the oil or mustard millers. Various other *Cruciferae*, as the *Myagrum sativum*, *Râphanus chrysæus* var. *oleifer* both cultivated in Germany the *Erysimum Sisymbrium officinale* *Turritis*, &c. might also be cultivated for both purposes.

6099. *The small or field poppy* (*Papaver Rhœas*; *Opium*, Fr.) and also the Maw seed (*P. somniferum* var. *Pavot*, Fr.) a variety of the garden poppy are, as we have seen (467) cultivated on the Continent as oil plants the oil being esteemed in domestic economy next to that of the olive. Other species might be grown for the same purpose. All of them being annual plants require only to be sown on fine rich land in April thinned out to six or eight inches distance when they come up according to the spaces kept clear of weeds till they begin to run and to have their capsules as they ripen gathered by hand and dried in the sun.

6100. *The sunflower* (*Helianthus annuus* *Turnsole*, Fr. and *Girasole*, Ital.) has been cultivated in Germany for its seeds, which are found to yield a good table oil its husks are nourishing food for cattle.

6101. *The A'ruchus hypogæa*, *Myagrum sativum*, *Hépers matronalis*, *Râphanus sativus oleifer*, and *Râcanus communis* are cultivated in France as oil plants.

#### SECT. IV. Plants used in Domestic Economy

6102. Among agricultural plants used in domestic economy we include the *Mustard* *Buck-wheat* or *Beech-wheat*, *Cress*, *Tobacco* *Chicory*, and a few others; with the exception of the first, they are grown to a very small extent in Britain, and therefore our account of them shall be proportionately concise.

SUBSECT. 1. *Mustard*. — *Sinapis* L. *Tetradymia Sinapis* L., and *Cruciferae* J. *Mustarde* or *Sineuf* Fr. *Senf*, Ger. *Sinapa*, Ital. and *Mostaza*, Span.

6103. There are two species of mustard in cultivation in the fields, the white mustard (*Sinapis alba*, fig. 805. a) and the black or common (*Sinapis nigra*, b). Both are annuals, natives of Britain and most parts of Europe and cultivated there and in China, for an unknown period. White mustard flowers in June, and ripens its seeds in July. Black mustard is rather earlier. Mustard is an exhausting crop but profitable when the soil answers, and especially in breaking up rich lowry lands, as it comes off earlier and allows time for preparing the soil for wheat. In breaking up very rich grass lands, three or four crops are sometimes taken in succession. It cannot, however be considered as a good general crop for the farmer, even if there were a demand for it, as, like most of the commercial plants, it yields little or no manure. The culture of black or common mustard is by far the most extensive, and is chiefly carried on in the county of Durham. The seed of the black mustard, like that of the wild sort and also of the wild radish, if below the depth of three or four inches, will remain in the ground for ages without germinating hence, when once introduced it is

difficult to extirpate. Whenever they throw the earth out of their ditches in the Isle of Ely, the bank comes up thick with mustard, and the seed, falling into the water and sinking to the bottom, will remain embedded in the mud for ages without vegetation.

6104. *No such history as mustard*, in its present form, was known at our tables previously to 1730. At that time the seed was only coarsely pounded in a mortar as coarsely separated from the integuments, and in that rough state prepared for use. In the year I have mentioned, it occurred to an old woman of the name of Germain, resident at Durham to grind the seed in a mill, and to pass the meal through the several processes which are resorted to in making flour from wheat. The secret she kept for many years to herself, and, in the period of her exclusive possession of it, supplied the principal parts of the kingdom, and in particular the metropolis, with this article, and George I. stamped it with fashion by his approval. Mrs. Clements on regularly twice a year travelled to London, and to the principal towns throughout England, for orders, on any tradesman's idea of the present day; and she sold her mustard to pick up not only a decent pittance, but what was then thought a tolerable competence. From this woman's residence at Durham, it acquired the name of Durham mustard. (*Mech. Mag.* vol. iv. p. 37)

6105. *Any rich loamy soil* will raise a crop of mustard, and no other preparation is required than that of a good deep ploughing and harrowing sufficient to raise a mould on the surface. The seeds may be sown broad-cast at the rate of one lippe per acre harrowed in and guarded from birds till it comes up, and hoed and weeded before it begins to shoot. In Kent, according to the survey of Boys, white mustard is cultivated for the use of the seedmen in London. In the tillage for it, the ploughed land is, he says, harrowed over and then furrows are stricken about eleven or twelve inches apart, sowing the seed in the proportion of two or three gallons per acre in March. The crop is afterwards hoed and kept free from weeds.

6106. *Mustard is reaped in the beginning of September* being tied in sheaves, and left three or four days on the stubble. It is then stacked in the field. It is remarked that rain damages it. A good crop is three or four quarters an acre the price from 7s. to 90s. a bushel. Three or four crops are sometimes taken running, but this must in most cases be bad husbandry.

6107. *The use of the white mustard* is or should be chiefly for medical and horticultural purposes, though it is often ground into flour and mixed with the black, which is much stronger and far more difficult to free from its black husks. The black or common mustard is exclusively used for grinding into flour of mustard, and the black husk is separated by very delicate machinery.

6108. *The French either do not attempt to separate the husk, or do not succeed in it*, as their mustard when brought to table is always black. It is, however, more pungent than ours, because that quality resides chiefly in the husk. The constituents of mustard seed appear to be chiefly starch, mucus, a bland fixed oil, an acrid volatile oil, and an ammoniacal salt. The fresh powder, Dr. Cullen observes, shows little pungency, but when it has been moistened with vinegar and kept for a day the essential oil is evolved, and it is then much more acrid.

6109. *The leaves of the mustard family* like those of all the radish and Brassica tribe, are eaten green by cattle and sheep, and may be used as pot-herbs. The habit is commonly burnt, but is better employed as litter for the straw yard, or for covering underdrains, if any happen to be forming at the time.

6110. *As substitutes for either the black or common mustard*, most of the Cruciferae enumerated when treating of oil plants (6098) may be used, especially the *Sinapis arvensis*, or charlock, *S. orientalis*, *chinensis*, and *drussicata*, the latter commonly cultivated in China. The *Raphanus Raphanistrum*, common in corn fields, and known as the wild mustard, is so complete a substitute, that it is often separated from the refuse corn and sold as Durham mustard seed.

Synonym 2. *Buck-wheat*. — *Polygonum Fagopyrum* L. *Oxalidaria Trigynis* L. and *Polygonum* J. *Blé noir* or *Blé d'arrasin*, Fr. (corrupted from Had-rasin, i. e. red corn, Celtic) *Buchmetzen*, Ger., *Miglio*, Ital. and *Trigo negro*, Span. (Ag 806.)

806

6111. *The buck-wheat* or more properly beech-wheat (from the resemblance of the seeds to beech mast, as its Latin and German names import), is an annual fibrous-rooted plant, with upright flexuous leafy stems, generally tinged with red, and rising from a foot to three feet in height. The flowers are either white or tinged with red, and make a handsome appearance in July and the seeds ripen in August and September. Its native country is unknown though it is attributed to Asia. It is cultivated in China and other countries of the East as a bread corn, and has been grown from time immemorial in Britain and most parts of Europe, as food for poultry and horses, and also to be ground into meal for domestic purposes. The universality of its culture is evidently owing to the little labour it requires: it will grow on the poorest soil, and produces a crop in the course of three or four months. It was cultivated in *Guend's time* (1597), to be ploughed in as manure: but at present, from its inferior value as a grain, and its yielding very little haulm for fodder or manure, it is seldom grown but by gentlemen in their plantations to encourage game. Arthur Young, however, "recommends farmers in general to try this crop. Nineteen parishes out of twenty, through the kingdom, know it only by name. It has

numerous excellencies, perhaps as many to good farmers, as any other grain or pulse in use. It is of an enriching nature, having the quality of preparing for wheat, or any other crop. One bushel sows an acre of land well, which is but a fourth of the expense of seed-barley. Its principal value is not so much in the crop as in the great good it does the land by shading it from the heat of the sun. When the wheat fallow can be perfectly cleaned before the middle of June, it is far better to sow the ground with buck-wheat than let it be bare, the wheat crop, whether the dung be laid on before or after the buck-wheat, will be one third better than without it. (J M)

6112. There are different species in cultivation, and *P. tataricum* (Ag 807 a.) is said by some to be nearly as productive as *P. Fagopyrum*. Von Thier, however is of a different opinion. In Nepal *P. esarginatum* (b) is cultivated. According to M. Desandolle, the farmers of Piedmont, especially in the valley of Lanzo, chiefly employ the *P. tataricum*; because it ripens more quickly and is therefore less likely to suffer from cold summers, or from being sown on the sides of the mountains. The Piedmontese distinguish the *P. Fagopyrum* by the name of "Formentine de Savoie," and the *P. tataricum* by that of "granoche," and "Formentine de Luerna." The principal objection to the latter is, that its flowers expand irregularly and unequally, and that the flour is blackish and rather bitter. The *P. Fagopyrum* is, however cultivated in the richest parts of Europe as a food for domestic fowls or other birds, rather than for the use of man. Cakes made of the flour of this species, we are told by Thunberg round, coloured, and tasted, are sold in every part of Japan. Loururo states, that *P. esarginatum* is cultivated throughout the kingdom of Cochinchina, as an excellent vegetable for eating with broiled meat and fish. (Bot. Reg.)

6113. In the culture of the buck-wheat the soil may be prepared in different ways, according to the intention of the future crop and for this there is time till the end of May, if seed is the object, and till June if it is to be ploughed in. It will grow on any soil but will only produce a good crop on one that is tolerably rich. It is considered one of the best crops to sow along with grass seed and yet (however inconsistent) Arthur Young endeavours to prove that buck-wheat, from the closeness of its growth at the top, smothers and destroys weeds, whilst clover and grass-seeds receive considerable benefit by the shade it affords them from the piercing heat of the sun!!

6114. The season of sowing cannot be considered earlier than the last week of April or first of May as the young plants are very apt to be destroyed by frost. The mode is always broad-cast, and the quantity of seed a bushel per acre it is harrowed in, and requires no other culture than pulling out the larger weeds, and guarding from birds till the reaping season.

6115. Buck-wheat is harvested by mowing in the manner of barley. After it is mown, it must lie several days, till the stalks are withered, before it is housed. It is in no danger of the seeds falling, nor does it suffer much by wet. From its great succulency it is liable to heat, on which account it is better to put it in small stacks of five or six loads each, than in either a large one or a barn.

6116. The produce of the grain of this plant, though it has been known to yield seven quarters an acre, may be stated upon the average at between three and four. It would be considerably more did all the grains ripen together but that never appears to be the case, as some parts of the same plant will be in flower, whilst others have perfected their seed.

6117. The use of the grain of buck-wheat in this country is almost entirely for feeding poultry, pigeons, and swine. It may also be given to horses, which are said to thrive well on it but the author of *The New Farmer's Calendar* says, he thinks he has seen it produce a stupefying effect.

6118. It has been used in the distillery in England and it is a good deal used in that way and also as horse-corn on the Continent. Young says, a bushel goes further than two bushels of oats and mixed with at least four times as much bran, will be full feed for any horse for a week. Four bushels of the meal, put up at 4 cwt. will fatten a hog of sixteen or twenty stone in three weeks giving him afterwards three bushels of Indian corn or hop-past broken in a mill, with plenty of water. Eight bushels of buck-wheat meal will go as far as twelve bushels of barley meal.

6119. The meal of buck-wheat is made into thin cakes called crumpits in Italy and even in some parts of England; and it is supposed to be nutritious, and not apt to turn acid upon the stomach. (Withering.)

6120. The blossoms of this plant afford a rich repast to bees, both from the quantity of honey they contain, and from their long duration. On this account it is much prized in France and Germany, and The Farmer advises his farmers to carry their hives to fields of this crop in the autumn, as well as to bush lands.

6121. The spikes of much-wheat is said to be more nourishing than clover when cut while in flower. Another says, it has a powerful insipidating quality. He has seen hops, after having and heavily on it, cause haem in such a state of intoxication as to be unable to walk without vomiting. The dried heads are not eaten readily by any description of animal, and afford but very little nutriment. On the whole, the crop is of most value when ploughed in green for the latter purpose.

6122. As a seed crop, the author of *The New Farmer's Calendar* seems justified in saying, it is only valuable on land that will grow nothing else.

**BREWER 3.** Tobacco. — *Nicotiana L.*; *Præhensilis Monagiana L.*, and *Solomon J. L.* Tabaco, Fr.; der Tabak, Ger. Tabacco, Ital.; Tabaco, Span.; and Potum or Potume, Brazil.

6123. The species cultivated are annuals, natives of Mexico, or other parts of America, and, according to some, of both hemispheres. It was brought to Europe early in the sixteenth century, after the discovery of America by Columbus, probably about 1519 from Portugal to France about 1560, by John Nicot, after whom the plant is named and to England, according to Lobel, about 1570 according to Hume by Ralph Lane, in 1586, from the island of Tobacco in the Gulf of Mexico, whence the popular name.

6124. The system of smoking is of unknown antiquity in Asia, Persia, and other eastern countries; but whether the plant used was tobacco is very doubtful. The natives of Mexico, in the present day not only use it as an article of luxury, but as a remedy for all diseases, and, when provisions fail them, for allaying the pains of hunger and thirst. The use of smoking was introduced to England by Capt. Lane, who had learned the custom in Virginia, in 1586. He brought home with him several pipes and taught the custom to Sir Walter Raleigh, who soon acquired a taste for it, and began to teach it to a friend. He gave, we are told, "smoking parties" at his house at Islington, when the guests were treated with nothing but a pipe and a mug of ale and nutmeg. (Rag. Hist.) Down to the time of Elizabeth, it was not uncommon for ladies to smoke. During the reign of James her successor, most of the princes of Europe violently opposed its use. James of England wrote a book against it; the Grand Duke of Moscow forbade its entrance into his territory under pain of the knout for the first offence and death for the next. The emperor of the Turks, the king of Persia, and pope Urban VIII. issued similar prohibitions, all of which were so ridiculous as those which attended the introduction of coffee, or Jew's bark. At present, all the sovereigns of Europe, and most of those of other parts of the world, derive a considerable part of their revenue from tobacco.

6125. The cultivation of tobacco on the Continent was not attempted except in gardens, till the beginning of the seventeenth century. Under Louis XIII. and XIV., its cultivation was allowed in certain provinces of France; and about the same time it was introduced as an article of cottage or spade culture, in Holland, Germany and part of Sweden. It also spread into Switzerland and Italy, and to various countries of the East. It is at present cultivated in almost every country of the world, but for commercial purposes chiefly on the Continent and islands of North America, and more especially in Virginia, Cuba, and St. Domingo. In no other parts of the world is it so well manufactured for the purpose of smoking as in Havana.

6126. In England the practice of planting and growing tobacco began to creep in in the time of Charles II. and an act was passed fixing a penalty of 10*l.* for every rood of land so cultivated, but making it lawful, however to grow small quantities, not exceeding half a pole, "in a physic or university garden, or in any private garden for physic or chirurgery." This act and others were confirmed by different acts during the reign of Geo. II. Notwithstanding this act, however, tobacco was much cultivated a few years prior to 1734, in the vale of York and Ryedale. In the latter district it did not excite the notice of legal authority and was raised and manufactured by a man who had formerly been employed upon the tobacco plantations in America; who not only cured it properly but gave it the proper cut, and finally prepared it for the pipe. But in the vale of York the cultivators of it met with less favourable circumstances. Their tobacco was publicly burnt, and themselves severely fined and imprisoned. Penalties it was said, were paid to the amount of 30,000*l.* This was enough to put a stop to the illegal cultivation of tobacco. But, perhaps rather unfortunately it has likewise put a stop to the cultivation of that limited quantity of half a rood, which the law allows to be planted for the purpose of physic and chirurgery or chirurgery.

6127. In Scotland, about the same time, tobacco was cultivated in various parts, more especially in the neighbourhood of Kelso and Jedburgh. Its produce was so great, that thirteen acres at Crailing fetched 104*l.*, at the low rate of 4*d.* per lb. (being 450 lbs. per acre) and would have brought more than three times as much, had not an act of parliament obliged the cultivator to dispose of it to government at that price. (Covey's Reports.)

6128. In Ireland, tobacco was introduced into the county of Cork, with the potato, by Sir Walter Raleigh, but the culture of the former does not appear to have made much progress, though according to Humboldt, it preceded that of the potato in Europe more than one hundred and twenty years, having been extensively cultivated in Portugal at the time that Sir Walter Raleigh brought it from Virginia to England in 1584. A writer in 1725, quoted by Brodigan, says, I have not heard that a rood of tobacco was ever planted in this kingdom. An act of George III. repealed several preceding acts, that prohibited the growth and produce of tobacco in Ireland; and this is the foundation on which Ireland now rests her claim to that branch of culture. Until the year 1783, Brodigan observes, the culture was limited; but in that year there were one hundred and thirty acres under tobacco and in 1789, one thousand acres in Wexford alone. "It has been partially cultivated in the adjoining counties of Carlow, Waterford, and Kilkenny, and in other places. In the province of Connaught an experiment was made in the vicinity of Westport. It has been grown in one or two instances near Dublin; in the northern section of the kingdom two or three trials have taken place on a small scale." And Mr. Brodigan, the author of the tract from which we quote has cultivated several acres in the neighbourhood of Drogheda, preparing the soil by horse labour as for turnips.

6129. The restrictive system will probably at no distant time, be removed from tobacco, and from every other crop; but that tobacco ever will enter into the general course of crops of the British farmer we do not think likely; because, when made in this, or in every thing else, is once made free, the tobacco of warmer climates will unquestionably be preferred to that of the British Isles. At present there is a number of petitioners in the House of Commons who use tobacco; but should its use become unfashionable among the higher classes, we should not be surprised to see an attempt made to lay such a tax on the foreign commodity as would give the landed interest a monopoly of an inferior article, which would thus be forced by the rich on the poor. We trust, however, to the growing political sense of the country to the force of opinion, in short, to the press, to avert such an evil. In the mean time, we extremely desire to see the culture of tobacco permitted and successfully attempted in Ireland, in order to aid in emptying the population of that country; and we should wish also to see every cottager in the three kingdoms growing his half rood, which the law permits, and which, at a moderate calculation, ought to produce 1*l.* of tobacco for his own smoking or snuff, or for selling to his neighbours. For this purpose we shall enter into the culture of tobacco at greater length than might otherwise be advisable.

6180. The annual species of tobacco, like the annual species of almost all dicotyledonous plants, may be grown in every country and climate because every country has a summer and that is the season of life for annual plants.

(Ag 808.) the common green tobacco (*Nicotiana glauca*)

809

In hot, dry and short summers, like those of the north of Russia and Sweden, tobacco plants will not attain a large size, but the tobacco produced will be of delicate quality and good flavour in long, moist, and not very warm summers, such as those of Ireland, the plants will attain a very large size, perhaps as much so as in Virginia, but the tobacco produced will not have that superior flavour, which can only be given by abundance of clear sunshine, and free dry air. By a skilful manufacture and probably by mixing the tobacco of cold countries with that of hot countries, by using different species, and perhaps by selecting particular varieties of the Virginian species, the defects in flavour arising from climate may it is likely, be greatly remedied.

6181. Species and varieties. The species almost every where cultivated in America is the *N. Tabacum* (Ag 808.) or Virginian tobacco, of which there is a variety or sub-species known as *N. macrophylla*, but of which we have never seen any plants. *N. glauca* is very generally cultivated almost to the exclusion of the other species in the north of Germany, Russia, and Sweden where almost every cottager grows his own tobacco for smoking. It also seems to be the principal sort grown in Ireland. There is a variety of it cultivated in *Wexford*, erroneously denominated *Oronoko*, and another commonly called *negro-head*. Both are very hardy and very productive, but the produce is not of a very good flavour. There are other species grown in America: the best *Havannah* cigars are said to be made from the leaves of *N. repanda* (Ag 810. a) a species introduced to this country from *Havannah* so late as 1821. The Indians of the Rocky Mountains of North America are said to prepare their tobacco from *N. quadrivalvis* (Ag 810. b) introduced in 1811, and *N. glauca* (Ag 810. c) introduced in 1803. These species are all annuals, and the last requires the protection of a greenhouse to make it ripen its seeds. There are several very distinct varieties, if not species, cultivated in the *Caracas*, of which some account by Mr Fanning, proprietor of the Botanic Garden of the *Caracas*, will be found in the *Gardener's Magazine* vol. vi. p. 327. There are also some other annual species, and some species of the genus *Petitia* which is nearly allied to the *Nicotiana* the leaves of which might be manufactured into very good tobacco. There can be little doubt that the *N. Tabacum*, the seeds of which may be purchased in every seed-shop, is some deserving the attention of the British cultivator as a first experiment.

6182. Soil. In a strict sense, the native soil of the tobacco is unknown in this country by which we mean the primitive earths or rocks to which it belongs. We are inclined to attribute it to alluvium and sand-stone rather than to clay or lime. In

810

Virginia the best tobacco is grown in a rich loamy, but rather light soil, which has been newly taken into cultivation. In Alsace, where we have seen stronger tobacco of the Virginian kind than in any other part of France or in Germany, the soil is a brown loam, rather light than heavy, such as would grow excellent potatoes and turnips, and which has been for an unknown period under the plough. Wherever potatoes or turnips may be cultivated, there we think tobacco may be grown.

6133. *Climate.* As it is beyond a doubt that the best tobacco is produced in countries within the tropics, it is evident that it cannot be worth culture in Britain in situations not naturally mild or warm. Tobacco can never be worth growing in situations much above the level of the sea, nor on wet springy soils or northern exposures.

6134. *Culture.* We shall notice in succession the practice in the West Indies, Virginia, and Maryland, in Alsace, in Holland, in the South of France, and in Ireland, as lately practised by Mr Brodigan, and suggest what we think the best mode. We shall draw our information chiefly from a valuable article in the *Nouveau Cours Complet d'Agriculture*, edition 1823, and from the treatise of T. Brodigan, Esq. 1830 looking into Carver's *Treatise on the Tobacco Plant*, 1779. Tatham's *Historical and Practical Essay* 1800. Jemmings's *Practical Treatise*, 1830, and our own notes of 1813-15, 18, 19, and 1828, on Sweden, Germany, and France.

6135. *Culture in the West Indies.* In the island of Tortuga, the tobacco seeds are sown in beds twelve feet square, and transplanted into the fields when about the size of young betanons, in rows three feet apart, and the plants three feet distant in the row. The soil is hoed till just clear of weeds, and the plants stopped when about a foot and a half high. The buds which push from the axillæ of the leaves are taken out with the finger and thumb, in order to throw the whole force of the plant into the leaves. When the edges and points of the leaves begin to get a little yellow the stalks are cut over by the surface when the leaves are wholly freed from dew they are then carried into a close house, so close as to shut out all air and hung upon lines laid across for the purpose of drying. When the stalks begin to turn brownish they are taken off the lines and put into a large bin or chest, and heavy weights laid on them for twelve days. They are then taken out, and the leaves stripped from the stalks, again put into the bin and again well pressed, and completely excluded from air for a month. They are now taken out and tied into bundles, of about sixty leaves in each, which bundles are kept completely excluded from the air in a box or chest till wanted for disposal to the manufacturer (*Dr Bertram, a contemporary of Sir Hans Sloane, is Jemmings, as quoted by Brodigan, p. 131.*) The species to which the above account refers, is, in all probability, the *N. repens*.

6136. *Culture in Virginia and Maryland.* New soil of a medium quality is preferred, the seeds are sown with six times their bulk of wood-ashes or sand, sown on beds of finely prepared earth, as early in spring as possible, and covered with straw branches, or boards at nights when any danger is apprehended from frosts they are of course kept clear of weeds. The field intended for the plants is in the mean time well laboured with the plough; it is laid into ridges three feet wide, and along the centre of each a row of plants is sown by means of a line marked with knots, at three feet apart the plants of the one row alternating with the intervals of the other, so that when the field is completed the whole stand in quincunx. The plants are taken from the seed-bed to the field when they have five or six leaves exclusive of the seed leaf but they may be transplanted with fewer or more leaves in moist or cloudy weather. They are taken up carefully raising the earth under them with a spade, and carrying them to the field in a basket, and they are planted with dibbers an inch in diameter and fifteen inches long. They are inserted as deep as the seed leaf, but no deeper. In a month afterwards they will have grown a foot in height, and will require to be hoed and weeded. When they have attained the height of two feet, the summit of each plant is pinched out, and the lower small leaves, and any others dirtied or injured by insects, picked off. From eight to twelve good leaves may now remain on each plant. The remaining part of the culture consists chiefly in removing weeds or insects, and in pinching out the buds which appear in the joints or axillæ of the leaves. From the time that the tops of the plants are pinched off, till that when the crop is fit to be gathered, is generally about five or six weeks. During this time the plants are looked over two or three times every week, for the purpose of pinching off the lateral buds, so as to confine the entire effort of vegetation to the nourishing of the eight or twelve leaves. When the leaves begin to change colour droop at the extremities, begin to smell rather more strongly to become furrowed rougher to the touch and easily broken when bent, the plants are cut over by the surface when the dew is completely removed from them. Some cut them an inch under the surface, and others an inch above it. Each plant is left on the spot where it is cut for one day and turned in the course of that day three or four times, to expose every part equally to get dried by the heat of the sun. Sometimes the plants are gathered into heaps, and remain on the field during the night in order to be spread out again the next day; but more generally they are collected together before the dew begins to fall, and put into a bin covered with boards on which stems are laid, and left in that situation, excluded from the air, for three or four days to ferment. Afterwards they are taken out, two and two tied together at the root and end of the stem, or the same effect produced by running a peg through them, then hung across lines or cross-beams, and thus dried in open shade. After the plants have been completely dried, they are taken down from the cords, poles, or beams to which they have been attached, in a moist day because if they were to be handled in a very dry day the leaves would fall to pieces, or crumble into powder. They are now spread on hurdles in heaps, and covered with mats for a week or two to sweat during this time the heap is frequently examined and turned, in order that every part may be equally heated and fermented, and no part burnt. This is said to be the most difficult part of the preparation, as it unquestionably is of the art of making hay; experience alone can teach its attainment. The fermentation being completed, the leaves are separated from the stems, the latter thrown away and the former separated into three classes, bottom leaves, top leaves, and middle leaves. These leaves are now dried under cover and tied together in bundles of ten or twelve, which are called mannos or hands; these are packed in regular layers into casks or boxes, and compressed so as to exclude all air by means of a round board of the same diameter as the interior of the cask, and which is every now and then put in and pressed down by means of a lever which communicates a pressure of between 300 and 400 pounds. This manner of close packing is essential for the preservation of the tobacco. The operation is always performed when the air is humid, because, as before observed, dried tobacco is extremely brittle. Good tobacco thus prepared no longer ferments, except very slightly in the succeeding spring or summer, and which is found to be an advantage. The finest tobacco is grown in the west of Virginia and Maryland, near the Alleghany Mountains, where the temperature, during its growing season, is between 60° and 70° (*Dr Coeur, Complet d'Agr. &c.*) The species in this case is unquestionably *N. glauca*.

6137. *Culture in the South of France.* Two species chiefly *N. glauca*, but sometimes *N. rusticus*. The culture is carried to a considerable extent, especially in the provinces of Guisard and Utrecht. The seed is sown in beds, ten feet broad, and of any convenient length; the depth of the dung of the bed is two feet, and the frame which is placed on it is sometimes covered with ashes, but more commonly with mats only during nights. The plants are transplanted into fields which receive a sort of garden culture

The surface is laid out into beds or ridges two feet and a half wide, with alleys between of nine inches or a foot. The beds are raised two feet above the alleys, and are composed of alternate layers of rich soil and dung rotten almost to mould. The direction of the bed is north and south, and on each two rows of plants are inserted at eighteen inches distance between the rows, and at the same between plant and plant; the plants of one row alternating with the interstices of the others. The summer culture is the same as in Virginia, but the gathering of the crop is differently performed. When the leaves have shown the usual symptoms of maturity the lowest, or those of the third quality and the middle leaves, or those of the second quality are stripped off and kept separate, and from four to six at top left on for some time longer. The leaves stripped off are separately dried, and in the mean time the plants watched, and every sucker or bud which makes its appearance pinched off. The top leaves, or those of the first quality are gathered when ready and all the remaining parts of the process with the three qualities is exactly the same as in Virginia. (Ibid.)

6132. *Culture in Alsace*, and generally in the north and west of France and south of Germany. The seed, chiefly of N. glabrum, is sown in March or even earlier in beds of fine mould in a garden, covered at night, and till it comes up, during day also, with straw mats. When it begins to come up, these are removed by nine o'clock in the morning, and put on again when the sun goes down. After the plants have produced their seed leaves, the straw mats are supported by hoops or rods, so as not to injure the plants. About the end of April, the plants will be found to have attained from two to four leaves, and of their seed leaves, and from this time to the middle of June is considered the season for transplanting them into the fields. The best crops, other circumstances the same, are obtained from plants transplanted before the middle of May. Both in Holland and Alsace, sheep's dung is found the best manure for the tobacco. The ground is made as fine as possible, not laid into ridges unless wet, and the plants are planted in rows, generally two feet and a half apart, and the plants alternating at the same distance in the row. Much of the value of the crop depends on the dryness and warmth of the summer: a good wise year being invariably a good tobacco year. In cold wet seasons many of the lower leaves become rusty or spotted, and though these do not always appear before the second fermentation, yet they ultimately become obvious by changing into holes after the last drying: their inferiority then becomes obvious to the purchaser. The top leaves alone are those used for manufacturing into snuff, and they bring much the highest price. These leaves generally remain on the plant till the twentieth of August, but the lower leaves are commonly gathered by the fifteenth of July. The tops of the plants are not generally reached off till about the beginning of August, and they continue gathering leaves from that time till they are interrupted by white frost. Every eight days after the operation of topping, the side buds are pinched off. After the leaves are gathered, they are tied on the spot in bundles according to their qualities and when they are taken to the drying shed they are again separated and packed, and all those of one quality threaded together on lines, leaving a space about the width of a finger between each leaf. The line is stretched with leaves are stretched from one side to the other of the drying shed, or lengthwise under the eaves of cottage roofs, which are made to project from one foot to three feet for the purpose of drying tobacco and maize. The more extensive growers have large sheds or barns on purpose, and these are always constructed with openings on all sides, so as to admit of the most perfect ventilation. When the air does not circulate freely among the leaves instead of drying yellow they dry green or black, lose their graceful colour, and the midrib become rotten and the whole leaf fails to pecore. Leaves which on the plant were most exposed to the sun and dews such as the top leaves, always dry to the finest yellow. The leaves remain in the drying sheds till the weather has become decidedly cold in November or December though some of the leaves of inferior qualities are frequently purchased for the manufacture of smoking tobacco in the month of October. But these must be immediately manufactured, otherwise when lying together they contract a bad smell. The threads of leaves being ready to take down, the leaves are not taken off the threads, but they are laid down in a humid mild dry on a dry very floor one above another to the depth of from fourteen inches to half a foot. Here they lie for some time being examined occasionally to see that they are not heating: if they heat, they are immediately hung up again: if they do not, they remain in that position till wanted by the manufacturer. Often indeed they are manufactured as soon as properly dried on the strings. (Ibid.)

6133. *The culture of tobacco in the south of France* is not materially different from what it is on the south banks of the Rhine. The tobacco of the south of France is naturally of a better quality, but the care taken of it by the cultivators especially in the drying and fermenting, being less than in less favourable climates, the quality becomes reduced, so that the tobacco of Alsace is preferred to that of Germany. The plants are cut over with all their leaves on as in Virginia, and they are hung up to dry in pairs across strings or beams. Being thoroughly dried, the leaves are separated tied up in hands, and laid in heaps to ferment. These heaps are placed on boarded floors raised three or four inches above the surface of the soil. They are made two feet broad and two feet high, the width requiring exactly two hands, half of the one hand overlapping half of the other and the ends or footstalks of the leaves of both being outwards. This operation is commonly performed between the fifteenth of November and the fifteenth of January and the tobacco remains in that state till it is purchased by the manufacturer. The manufacturer having agreed for the price, makes up the hands into round balls of three or four hundred pounds weight, takes these hands, unties them separates the leaves, classifies them according to their qualities, and finally puts them in hogsheads, packing them closely by means of presses. In these hogsheads the tobacco remains till taken out to be made into snuff, cigars, or common smoking tobacco.

6140. *The culture of tobacco in Ireland*, as practised by Brodigan in Meath, is thus given. Hobbs like those made for cucumbers are to be prepared in March, and the seeds, Mr. Brodigan does not seem to have known what species he cultivated, sown any time from the fifteenth of that month to the first of April. In the beginning of May the plants may be hardened by exposure to the air and by the fifteenth or twentieth of that month they may be transplanted into the open field without injury. Forty thousand plants fit for transplanting may be raised on an acre of one hundred square feet. According to Carver a square yard will rear about five hundred plants, and allow proper space for their nurture till they are fit for transplanting. The field was prepared in every respect the same as for turnips, the drills or ridges were eighteen inches apart, and the manure, of which a good supply was given, buried in the centre of each ridge. The plants were put in with spades, at eighteen inches apart, along the centre of the ridge, and afterwards watered. "The planters were followed by women, with their aprons full of long grass, with which they covered each plant, and confined it by placing a stone or lump of earth at both ends: this covering is indispensable, unless the weather prove wet and cloudy. Such is the extreme delicacy of the plant, that it will not bear the heat of the sun until it has so far set in the soil as to be able to supply the loss by evaporation. This will not be for some days, during which time the cover cannot be safely removed. When the extent of a pint a plant, may be daily used. Some of the respectable planters in the county of Wexford have used pots as a covering for the plants, of which some thousands will be necessary. Others have used large oyster shells, cabbage, or dock leaves. I tried all these methods, and experience has satisfied me that the mode I practised has decided advantages. It protects the plant sufficiently against the sun, and the water passes freely through it: whereas where pots or leaves are used, they must be removed to admit water, and in case of rain the plants receive little or no benefit from it. The operation of planting may be continued until the twentieth of June, but the earlier the better after the frosts have passed away. In America and France, I found that four months were generally considered as necessary for the nutrition of the plants and that time in the climate cannot be allowed, unless they are put down early." (p. 160.)

6141. *The summer management of tobacco*, by Mr. Brodigan consisted in loosening the soil about the plants, removing the weeds, watering: "for weeks together" taking off the decayed leaves at bottom, topping when the plant has from nine to fourteen good leaves, and removing the side buds as they appear.

6143. *The curing process, by Mr. Brodigan, is as follows:—*About the middle of August, the plants having attained their full size, four or five of the bottom leaves of each plant are taken off "advised to be on the second or sunny side; and when they lose their bitterness, they are carried home to a barn, and there put in a heap for fermentation. The heap is turned, placing that in the centre which was before in the bottom or exterior and the temperature is not allowed to exceed 100° or 110°. After remaining two or three days in this heap, the leaves are spread out and cooled, and strung by the middle on lines of packthread; they are then hung up in an airy shady place, roofed in. When the leaves thus suspended have acquired an ashy colour they are fit for a second fermentation. "A quantity of hay must be placed between the tobacco and the ground, and the heap may be made of an oblong or conic figure, the end of the stems being placed inwards. The heap being made, it is to be surrounded with hay blankets, or other close covering. The period for this fermentation will depend upon the state of the weather and the dryness and size of the leaves. In four or five days I generally found the heat sufficiently high to penetrate and reduce the stems, and when that is accomplished the heap is to be cooled by spreading it out to dry. In reducing very strong tobacco, I found it necessary to permit the heat to ascend to 120°. In 60 hours I found the heat had abated 110° and in 72 hours, 150°; but the general range of the second fermentation was from 150° to 130° Fahrenheit. In some cases I had to resort to a third fermentation of the same tobacco, but the heat did not rise beyond 100°. Upon this important point of fermentation, or sweating the tobacco, I have given the result of my practice. For greater accuracy, and the benefit of the inexperienced, I have given it from a thermometer; but, at the same time, the hand and feeling of a practised overseer can direct the process. As soon as the tobacco has been perfectly dried, by exposure to the sun and the weather it is still necessary to dry any remaining moisture in the air-dries, for which purpose they must be packed so as to be outside, that the air may have its influence upon them. When they are perfectly dry and hard, the tobacco may be considered as fit for use, although it will possess more or less of crudeness until the month of March following. To correct this crudity or any extraneous that may exist, different preparations are used in different countries. In Brazil the leaves are steeped in a decoction of tobacco and gum copal. In Virginia, I understood they sprinkle the tobacco, in the packing process, with diluted rum and molasses, and in Ireland they sprinkle, in the packing process, with a decoction of the green tobacco stems, or a decoction of hay with a small portion of molasses; the effect of this innocent application is to soften and improve the flavour, darken the colour of the tobacco, and render it, in appearance, a more merchantable commodity. The next and last operation is to tie the leaves in hands, and pack them in bales or portable packages." (p. 165.)

6144. *Improvements in the curing process.* Some of Mr. Brodigan's tobacco, he informs us, only wanted age to be as good as Virginia. Tobacco improves by a sea voyage, as it undergoes a certain degree of fermentation in the bales in the spring or summer months. Drying houses heated by stoves or steam, as now erected in America, he thinks would be an improvement in Ireland. Captain Hans Hall visited a tobacco plantation on James River and found the house in which the *Amado* were hung up with fires of wood made upon the earthen floor. The flavour of the wood burnt in this way Mr. Brodigan states, is now strongly perceptible in the tobacco of late years imported from America.

6144. *As suggestions derived from considering what we have read and observed on the subject of cultivating and curing tobacco, we submit the following*

6145. *Where a farmer who thoroughly understands and successfully practises the Northumberland mode of cultivating turnips, intends growing tobacco as a field crop, we would recommend him to prepare the soil exactly as for Swedish turnips, give a double dose of well rotted manure, mix the seed with fifty times its bulk of sand or bone dust, and sow with Common's turnip drill usually called French's, about the middle of May. When the plants come up, they may be thinned out as turnips are, to sixteen or eighteen inches apart, and topped in the beginning of August. The rest of the process may be conducted as in Alsace, drying, however, in a barn or house heated by an iron stove. A cottager or spade cultivator may find it worth his while to sow in a bedded or in a flower pot, and transplant, he may dry his leaves the first time under the eaves of his cottage, and the second time in his garret; or if the quantity is small for home use, in his kitchen. For his tobacco liquor or sauce he may grow a score or two of poppy plants, collect the opium from them, and mix this with whisky or spirit of any kind, in which abundance of peach leaves, or a few leaves of *Laurus nobilis*, or one or two of the common laurel, have been infused, adding water and salt as directed above. A gardener where there are hothouses and hothouse shade, may dry and ferment his stems and indeed whole and seeds of *N. repandum*, he ought to grow better tobacco than any person whatever not in Virginia or the West Indies.*

6146. *Produce.* According to Morse (*American Geography*) "An industrious person in Maryland can manage 6000 plants, which, at a yard to each plant, cover considerably more than an English acre of ground — the produce of these 6000 plants is 1000 lbs. of tobacco. "A hoghead, says Warden, 'weighing 1350 lbs., is considered a good crop, and sufficient employment for one labourer. In general four plants will yield a pound, though very rich land will yield double the quantity. On the fresh, rich lands of Kentucky from 1000 to 1500 lbs. are raised per acre." (Brodigan p. 189.) The leaves of four plants in Virginia make one pound of tobacco. According to Brodigan, the average produce in the county of Wexford is 1200 lbs. per English acre. In Meath, he has had 1680 lbs. per English acre. The money cost of production he estimates at 18s. where the land is prepared by horse labour and 30s. where it is prepared by manual labour, per English acre. The produce, at 16s. 8s. per hoghead of 1350 lbs. barely pays the expense.

6147. *To save seed.* Allow a few of the strongest plants to produce their flowers, they will have a fine appearance in July and August, and in a favourable season each plant will ripen as much seed in September as will sow a quarter of an acre by the drill system of culture, or stock half a dozen acres by transplanting.

6148. *The value of tobacco as an agricultural crop is much diminished, from the circumstance of its producing no measure.*

6149. "The arguments of the immortal Joffrion against the culture of tobacco, and in favour of wheat, have their weight in Virginia, where manure is not to be procured in proportion to the demand, and where the produce of that state has to enter into competition with that of the fresh lands of the western country. It is perfectly true, that where tobacco is generally cultivated, his picture of wretchedness is realized. It is the same in France, in the wine districts, where the people, from the want of corn, and the hops, poultry and other essential commodities it produces, are the most wretched of any in that country. It is with tobacco in America as with sugar in the West Indies, both are cultivated from their relative advantages over other crops. Sugar is more profitable than tobacco in the West Indies, although the tobacco grown there is of superior quality, and tobacco is preferred in America to wheat, where the soil and climate admit its cultivation. In some situations it is grown as a matter of necessity such is the richness of their alluvial and fresh lands, that wheat cannot be produced until that excess of fertility is reduced by a course of

tobacco, maize or hemp" (*Brodigan*, p. 84.) The farmers of Virginia, as the immortal Jefferson predicted (*Edict of Virginia*) have now ascertained that it is better to raise wheat at one dollar a bushel than tobacco at eight dollars per hundred weight. (*Ibid.* p. 127.) As a source of labour, Mr. Brodigan thinks the culture and cure of tobacco a desirable employment for the rural population of Ireland. Its great advantage is that it affords employment for those intervals when the labouring poor are at present destitute of occupation. "The cultivation of a potato crop is of vital importance to the Irish peasant, but as soon as that crop is planted there is a long interval of idleness and distress. The stock of potatoes is then generally exhausted or unfit for use, and the summer months are the most pinching times with the poor. The planting of tobacco may be said to commence when the other is furrowed and the field management occupies the interval until the corn-harvest. Again, between the corn harvest and the taking up of the potatoes there is another interval of idleness, and that is occupied in the curing of the tobacco." (*Brodigan*, p. 178.) As a cleaning crop and a preparation for wheat, it must be at least equal to the potato.

6150. *The analysis of the tobacco stalk* is given by Mr. Brodigan on the authority of Mr. Davy of Dublin. The object was to ascertain whether the stalks contained any quantity of the tannin principle of alkali or of any useful vegetable substance.

6151. *The presence of the tannin principle* could not be detected, and the alkali afforded was not very considerable. One thousand parts of the stalks yielded fifty-eight of ashes, which afforded three parts and a quarter of alkali mostly potash. The stalks contain nearly one tenth of their weight of tobacco and where tobacco is employed either in fumigating or in making decoctions for the destruction of insects, it may be useful to know that ten parts of the stalk will always produce effects equal to one part of the leaves.

6152. *Diseases and enemies.* In Virginia, the diseases and injuries to which tobacco is liable, are, in the language of the planter worm holes, ripe-shot or sun-burnt, moon burnt, house-burnt, stunted by growth, torn by storms of hail or wind, injured or killed by frost. In Ireland we are exempt from those damages, except what may arise from heavy gales, which, in exposed situations, lacerate and break off the leaves or an early frost, which is seldom injurious before Michaelmas, at which time if the planter be careful, he can have his tobacco off the ground." (*Brodigan*, p. 197.)

6153. *The same writer however enumerates the enemies of the tobacco in Ireland, as "the red or ring worm, which is so destructive in some situations to wheat and corn crops, the grub, slug, caterpillar and the tobacco-worm. Where the first two predominate in the soil, it is better not to plant tobacco; for there is no effectual mode of arresting their ravages. A correspondent in the county of Wexford has informed me, that two gentlemen in his neighbourhood attempted the planting of six acres of tobacco this last season, and the plants were no sooner put down than they were cut off by the red worm. they planted again, and the same fate attended them. they planted a third time, and they were a third time destroyed. Thus all their labour and expense were lost and in the month of July they sowed the ground with turnips. The grub, or root-worm as it is called marches from plant to plant beneath the soil, secures from observation, he attacks the roots of the plants when grown to a considerable height and thus prostrates a whole field. Where numerous, it is in vain that you seek for the enemy but as soon as the plant appears sickly it is advisable to pull it up, and you are likely to meet a pair of grubs, as they are companionable travellers. The other enemies are visible, and not so destructive. The slug attacks the young plants in the seed-bed and in the field and devours the young leaves he will also cut the leaves of the tobacco in every stage of its growth which is a proof that its caustic or poisonous property does not attach to it in the green state. The caterpillar generally appears in the warm month of July, it is large and of a graceful aspect. As soon as the leaves appear perforated, this enemy must be sought for, and he will be found in the day-time in the shaded parts of the plants. The caterpillar appears to exist only in close and warm situations." (*Brodigan*, p. 181.) Lime-water or cow urine effectually destroys slugs, snails, and worms, and probably some of the sorts of caterpillars.*

6154. *The manufacture of tobacco* we have slightly described in the *Encyclopædia of Plants*. We have since had an opportunity of witnessing the progress of all the different operations carried on in preparing shag and other kinds of smoking tobacco pig-tail and other chewing tobacco, various snuffs, and different kinds of cigars, in one of the most extensive manufactories in London and the conviction on our mind is, that very little in the way of manufacturing can be attempted by the gardener or cottager. That little we shall shortly describe.

6155. *The tobacco*, being properly fermented and cured may be kept closely pressed and excluded from air in casks, till wanted; or when the curing process is completed, smoking tobacco and snuff may be made from it as follows. — Open out the leaves singly, and from each tear out the midrib. The midribs are better adapted for rapping into snuff than for cutting into shag for smoking and being scented by any essence, such as that of thyme, anise, lemon, or more especially by that of the root of *Fris scortellia*, the roots root of the druggists may be tied up in what are called carrots, or rolls, about eighteen or twenty inches long, two or three inches in diameter in the middle, and half an inch at each end. They are tied with packthread drawn as tight as possible, and the threads quite close so as to compress the tobacco into one solid substance, and completely to exclude the air. When snuff is wanted, unroll a part of the packthread at one end, and rasp the tobacco into snuff with a file or grater. The snuff may then be laid in a dry place till wanted for a fresh supply. The soft parts of the leaves may be treated in the same manner and a snuff produced which some prefer to the other. Gardeners may dry leaves of any odiferous plant, such as thyme, mint, *Achillea* citharedra, &c., and tie them up in the tobacco carrot as substitute tea for liquid essences; and, if thought necessary they may add a leaf or two of *Peritrum album* to add pungency. For cottagers, there are artemisia wild thyme, and various other plants, which may be added. The soft parts of the leaves, from which the midribs have been removed may be slightly sprinkled with water without any admixture whatever and twisted into a rope, about the thickness of a common straw rope. The rope may then be coiled up in a ball, as firmly and compactly as possible, tied round in two or three places with packthread, wrapped in paper and placed in a dry situation excluded from the air till wanted for use. When to be used for smoking cut off a few inches of the rope, open it out, and cut it into shreds with a knife or chopper, so that it may resemble shag tobacco. If it is to be made into snuff open out the leaves, dry them over the fire or in an oven and pound them in a mortar adding to the powder any scented water or volatile odiferous oil, as pleasure. If more snuff is made than is wanted for immediate use, put it in a glass bottle and cork it closely. In manufacturing snuff various matters are added to give it an agreeable scent, and hence its numerous varieties. The three principal kinds are rappee, Scotch, or Spanish, and third. The first is only granulated the second is reduced to a very fine powder and the third consists of the shavings of the second sort. The Scotch and Irish snuffs are, for the most part, made from the midribs the Strasburgh, French and Russian snuffs from the soft parts of the leaves.

6156. *The process of forming cigars* is very simple; but, as it cannot be done well without much practice, it would be of little use to offer a description. Whoever wishes to make himself master of all that is known on the culture of tobacco in different parts of the world and all the different modes of its manufacture.

two, may consult *Cours d'Agriculture Complet*, Paris, 8vo, edit. 1823, art. Trian; *Coursus Pratique*, London, 8vo, 1779; *Trotter's Essay*, London, 8vo, 1805; the *Experimental Farming Course*, 2d ed., or *First*, *Second*, and *Practical Instructions for making twenty five acres of clover according to the latest improvement*, Chesham, Knebworth, 1824, 8vo; *Schmidt's Tobacco Culture of the French and Dutch countries, with the Mode of preparing the Plant for Use*, Dresden, 8vo, 1824. Arnold. The two latter works are in German.

**Summary. 4. Other Plants used in Domestic Economy, which are or may be cultivated in the Fields.**

6157. Many garden plants might be cultivated in the fields, especially near large towns, where manure is easily procured, and a demand for the produce exists. Among such plants may be mentioned the cress, parsley, onion, leek, lettuce, radish, &c. There are also some plants that enter into the agriculture of foreign countries where the climate is not dissimilar to our own, which might be very effectually cultivated in this country were it desirable. Among these is the chaccory, the roots of which are used as a substitute for coffee. The lettuce might be grown for its milky juice, as a substitute for or rather a variety of opium. Of dwarf fruits, as the strawberry currant, gooseberry, raspberry, &c., we said nothing here, having already alluded to them in treating of orchards.

6158. The agriculturist who attempts to grow any of the above plants can hardly expect to succeed unless his knowledge extends beyond the mere routine of country husbandry, either by reading and the study of the nature of vegetables, or by some experience in the practice of gardening. No farmer on a moderately extensive scale will find it worth while to attempt such productions, whatever may be his knowledge or resources; and for the garden-farmer or the curious or speculative amateur we would recommend observation and enquiry round the metropolis, and the reading of books on horticulture. All that we shall do here, will be to give some explanation of the culture and management of cress and chicory.

6159. The garden cress (*Lepidium sativum* L.), too well known to require any description, is grown in the fields in Essex, the seed being in some demand in the London market.

6160. It is sown on any sort of soil, but strong loam is the most productive. After being well pulverized on the surface, the seed is sown broad-cast and lightly harrowed in. The season of sowing for the largest produce is March, but it will ripen if sown the first week in May. The quantity of seed to an acre varies from two to four pecks, according to the richness of the land; the seed will not grow the second year. No after-culture is required but weeding. The crop is reaped and left in handfuls to dry for a few days, and then thrashed out like rapeseed or mustard in the field.

6161. The use of the cress seed is chiefly for sowing to cut for young turkeys; and for forcing salads by the London cooks on hot metal funnels and porous earthenware vessels. A very considerable quantity is also used in horticulture, it being one of the chief early salads, and cut when in the seed leaf. The haulm is of very little use as litter, and, on the whole, the crop is exhausting.

6162. The culture of the chicory as an herbage plant has already been given (5514.) when grown for the root to be used as a substitute for coffee, it may be sown on the same soil as the carrot, and thinned out to the same distance as that plant.

6163. These roots are taken up in the first autumn after sowing in the same manner as those of the carrot. When they are to be manufactured on a large scale, they are partially dried and in that state sold to the manufacturers of the article, who wash them, cut them in pieces, roast them on a kiln, and grind them between stoned rollers into a powder which is packed up in papers, containing from two ounces to three or four pounds. In that state it is sold either as a substitute for coffee, or for mixing with it. But when a private family cultivates the plant for home manufacture the roots are laid in a cellar among sand and a few taken out as wanted, washed, cut into slices, roasted in the coffee roaster till they become of a brown colour and then passed as wanted through the coffee mill.

6164. The value of the chicory as a coffee plant, Von Thuer observes in 1810, is proved by its having been cultivated for that purpose for thirty years. Dr. Henslow has written some curious papers on the subject in *The Calcuttana Horticultural Memoirs* (vol. iv.) and both that gentleman and Dr. Duncan approve of its diastetic qualities. The former indeed says, he thinks it preferable to coffee, which may be a matter of taste, as some prefer the flavour of the powdered roots of dandelion to that of either coffee or chicory. Dr. Duncan is of opinion that chicory might be cultivated with great national advantage as a substitute for the coffee berry (*Dance to Calcutt. Hort. Soc.* 1821). He says the decoction of chicory roots is wholesome, but that it has nothing more belonging to it of coffee than the colour. He sees no objection to its use as a substitute, but deprecates its mixture with the powder of real coffee.

6165. The value of the chicory as a salad plant appears to us not to be sufficiently appreciated in this country. Great quantities of the blanched leaves of chicory are sold in the markets of the Netherlands very early in the spring, and supply a grateful salad long before lettuce are to be had. The roots are taken up on the approach of winter and packed in cellars in alternate layers of sand, so as to form ridges with the crowns of the plants on the surface of the ridge. Here, if the frost be excluded, they soon send

811

812

6166. The *Astragalus hibernicus* (Fig. 812.), an annual distinguished by its triangular pods, a native of the south of Europe, is cultivated in Hungary (1690.), and in some parts of Germany, for the seeds as a substitute for coffee. The culture is the same as that of the common pea or tares.

6167 In a former section (6055) we have hinted that no farmer who cultivates the hop need be without a vegetable equal to asparagus, or fibre similar to that of flax to employ his servants in spinning; and from the foregoing observations it would seem that whoever has a garden may grow his own coffee and tobacco.

Sect. V. Plants which are or may be grown in the Fields for Medicinal Purposes.

6168. A number of medicinal plants were formerly grown in the fields; but vegetable drugs are now much less the fashion a few powerful sorts are retained, which are either collected wild or are natives of other countries, and the rest of the pharmacopœia is chiefly made up of minerals. It may safely be affirmed that there are no plants belonging to this section which deserve the notice of the general farmer but we have thought it desirable to notice a few sometimes grown by farming gardeners, and which may be considered as belonging almost equally to horticulture and agriculture, or as points of connection between the two arts. These are the saffron, liquorice rhubarb, lavender, mint, chamomile, and thyme.

6169. The saffron, or autumn crocus (*Crœcus sativus* L. fig. 813. a), is a bulbous-rooted

perennial which has been long cultivated in the south of Europe, and since Edward III. time in England, and chiefly at Saffron Walden in Essex. It was abundantly cultivated there, and in Cambridgeshire, Suffolk and Herefordshire, in the beginning of the seventeenth century but the quantity of land under this crop has been gradually lessening for the last century and especially within the last fifty years, so that its culture is now almost entirely confined to a few parishes round Saffron Walden. (Young's Essex) This is owing partly to the material being less in use than formerly and partly to the large importations from the East, often, as Professor Martyn observes, adulterated with bastard saffron (*Cyrtanthus tinctorius*) and margolds (*Calendula officinalis*).

6170. The bulbs of the saffron are planted on a prepared soil, not pure nor a very stiff clay but, if possible, a hard mould on chalk. They are planted in July in rows six inches apart across the ridges, and at three inches distance in the rows.

6171. The flowers which are purple, and appear in September are gathered carried home, and the stigmas picked out, together with a portion of the style these are dried on a kail between layers of paper and under the pressure of a thick board, to form the mass into cakes.

6172. The crop of an acre averages two pounds of dried cake after the first planting, and twenty-four pounds for the next two years. After the third crop the roots are taken up, divided, and replanted.

6173. The uses of saffron in medicine, domestic economy and the arts, are various. It is detergent, resolvent, anodyne, cephalic, ophthalmic, &c. but its use is not without danger in large doses it promotes drowsiness, lethargy vomiting, and delirium; even its smell is injurious, and has been known to produce syncope. It is used in sauces by the Spaniards and Poies here and in France it enters into creams, baccals, conserves, liquors, &c. and is used for colouring butter and cheese, and also by painters and dyers.

6174. The liquorice (*Glycyrrhiza glabra* L., fig. 813. b) *Liquoritia officinalis* H. B. 10493 is a deep-rooting perennial, of the Leguminosæ, with herbaceous stems rising four or five feet high. It has long been much cultivated in Spain and since Elizabeth's time has been grown in different parts of England.

6175. The soil for the liquorice should be a deep sandy loam, trenched by the spade or plough or the aid of leech, to two and a half or three feet in depth, and manured if necessary. The plants are procured from old plantations, and consist of the side roots, which have eyes or buds. In autumn, when a crop of liquorice is taken up for use, these may be taken off and laid in earth till spring, or they may be taken from a growing plantation as wanted for planting. The planting season may be either October or February and March. In general the latter months are preferred. The plants are dibbled in rows three feet apart, and from eighteen inches to two feet in the row according to the richness of the soil. The after-culture consists in hoeing, hoeing and deep stirring, in weeding, and in cutting over and carrying away the haulm every autumn after it is completely withered. As the plants do not rise above a foot the first season, a crop of onions or beans is sometimes taken in the intervals. The plants must have three summers growth at the end of which the roots may be taken up by trenching over the ground. These are either immediately sold to the brewers, druggists, or to common druggists, or preserved in sand, like carrots or potatoes, till wanted for use. They are used in medicine and yarrow-brewing.

6179. The *rhubarb* (*Rheum palmatum* L., fig. 813. c) is a perennial, with thick oval roots which strike deep into the ground, large palmate leaves, and flower-stems six or eight feet high. Its leaves are the best of all the kinds of rhubarb for tart. The Society of Arts erected itself for many years to promote the culture of this plant, as did Dr Hope of Edinburgh. It has accordingly been cultivated with success both in England and Scotland; though the quality of the root produced is considered by the faculty inferior to that of the Russia or Turkey rhubarb, as Professor Martyn thinks, an inferiority probably owing to the moisture of our climate, and the imperfect mode of drying.

6177. In the culture of this plant, if bulk be produce be the object, then a deep, rich loamy sand should be chosen; but if flavour then a dry, warm, somewhat calcareous sand. Prepare as for liquorice, and sow in patches of two or three seeds, in rows four feet apart, and the same distance in the rows. Transplanting from seed-beds may be adopted, but the roots are never so handsome and entire. As soon as the plants appear, leave only one in a place. The plants will now stand in the angles of squares of four feet to the side. The after-culture consists in hoeing and deep stirring, both lengthwise and across; in ploughing in the same directions. In never letting the flower-stems rise higher than two feet, or show flowers or seed unless some is wanted for propagation, and in removing the decayed leaves every autumn. The plants, having stood three or four summers, may be taken up, and their main roots dried in a very slow manner by way of the following modes. — The common British mode of curing or drying the rhubarb, after cleaning the roots, is to cut them into sections, an inch or more in thickness, slice them, and dry them in airy lofts, larders, or kitchens, in a gradual manner. This has long been the practice of private gardeners who grow the root for their own use and has also been adopted by cultivators for the druggists. The rhubarb is cured in Turkey by being thoroughly cleaned, the smaller branches cut off, and then cut transversely into pieces of a moderate size — these are placed on long tables or benches, and turned three or four times a day that the yellow viscid juice may incorporate with the substance of the root. If this juice be suffered to run out, the roots become light and unserviceable, and if they be not cut within five or six days after they are dug up, they become soft and decay very speedily. Four or five days after they are cut, holes are made through them and they are hung up to dry exposed to the air and wind, but sheltered from the sun. Thus, in about two months, the roots are completely dried, and serve at their full perfection. The loss of weight in drying is very considerable — seven loads of green roots yielding only one small barrel load of perfectly dry rhubarb.

6178. The Chinese in curing rhubarb, after having cleaned the roots, by scraping off the outer bark, as well as the thin yellow membrane underneath, cut them in slices, an inch or two in thickness, and dry them on stone slabs, under which large fires are kindled. They keep continually turning these slices on the warm slabs, but as the operation is not sufficient to dry them thoroughly they make a hole through them, and suspend them on lines, in a place exposed to the greatest heat of the sun till they are in a condition to be preserved without danger of spoiling. A copious account of all the experiments made in Britain for the culture and curing of the rhubarb up to 1825, is given by Professor Martyn, in his edition of *Miller's Dictionary*.

art. *Rheum* and of the Turkey Russian, and Chinese rhubarb, in *Thomson's Dispensatory* 3d edit. 1825, p. 468. It has been alleged of late, that the true medicinal rhubarb is not the *Rheum palmatum* as hitherto supposed, but the *R. australe* (fig. 814.) This species appears to be peculiar to the great table lands of central Asia, between the latitudes of 31° and 40° where it is found to flourish at an elevation of 11,000 feet above the level of the sea. Large quantities of the roots are annually collected for exportation in the Chinese provinces, within the lofty range of the Himalaya. The best is that which comes by way of Russia, as greater care is taken in the selection, and on its arrival at Russia, within the Russian frontiers, the roots are carefully examined, and the damaged pieces removed. Mr Sweet has been informed that the stems of the leaves have the same effect as the root, only of course, a greater portion of them will require to be used. They may be made up in a small tart, like the stems of the common rhubarb. (*Gard. Mag.* vol. v. p. 161.)

6179. The *lavender* (*Levándula Spica* L., fig. 813. d) is a dwarf odorous shrub of three or four years' duration, grown in the fields in a few places round London, and chiefly in Surrey, for the spikes of flowers used by the druggists, perfumers, and distillers. The soil should be a poor dry calcareous gravel. The seeds should be sown in a garden in spring, and the plants may be transplanted in September or March following, in rows two feet apart, and kept free from weeds. The second season they will yield a few flowers, and a full crop the fourth, after which the plants will continue productive for five or six years. The spikes are gathered in June, dried in the shade, and sold in bundles to the herbalists, druggists, &c.

6180. *Thyme*, *wormwood*, *majoram*, *savory*, and some other aromatics, are cultivated in the same manner, and for similar purposes. Being usually smaller plants, they should be planted closer, but to have much flavour the soil must be dry and calcareous.

6181. *Chamomile* (*Anthemis nobilis*) is a creeping perennial grown for its flowers. It only requires to be planted on a poor soil, in rows a foot apart, and hoed between. It will produce abundance of flowers annually from June to September, which are gathered, and dried in the shade. They are sold by weight to the druggists and apothecaries. The double-flowered variety is, from its beauty, that commonly cultivated but the single possesses more of the virtues of the plant according to its weight.

6182. The *mints* (*Mentha*), and especially the *peppermint* (*Mentha piperita*), are creeping-rooted perennials, cultivated on rich marshy or soft black moist soils for distilling. The plants are grown in beds with trenches of a foot or more in width and

depth between, or as to result of irrigation. The sets are obtained from old plantations and placed in rows across the beds at six inches' distance every way, in March or April. No produce worth notice is obtained in the first year, but a full crop in the third, and the plants will continue to produce for five or six years. The spikes of flowers, and in some cases the entire herbage, are cut over in June, as soon as the flowers expand, and carried immediately to the druggist's mill. Some growers distil it themselves.

6183. The common aster (*Faleria officinalis* L.) is sometimes cultivated for its roots for the druggists. It is a native plant, and prefers a loamy soil. Its Dutch name is *astor*, which are either procured from the offsets of former plantations, or from wild plants found in wet places in the neighbouring woods, are planted six inches asunder, in rows twelve inches apart. Soon after it comes up in the spring the tops are cut off to prevent its running to seed, which would spoil it. At Michaelmas, the leaves are pulled and given to cattle, and the roots dug up carefully, and clean washed; the remaining top is then cut close off, and the thickest part set down to facilitate their drying, which is effected on a kiln, after which they must be packed tight, and kept very dry, or they will spoil. The usual produce is about 18 cwt. per acre. This crop receives manure in the winter and requires a great deal.

6184. The orchis or salep plant (*Orchis mascula* L.) is a tuberous perennial, which grows plentifully in moist meadows in Gloucestershire, and other parts of the country. It flowers in May and ripens seeds in July. It has been proposed to cultivate it for its tubers to be used as salep but the plant is very difficult of propagation from seed, and can hardly be multiplied at all by the root and, though it may answer to collect the tubers and prepare them, it is not likely their culture will ever pay. As the plant is very abundant in some situations, it may be useful to know its preparation, which is thus described in *Phil. Trans.* vol. lix.

6185. The bulb is to be washed in water, and the fine brown skin which covers it is to be separated by means of a small brush, or by dipping the root in hot water and rubbing it with a coarse linen cloth. When a sufficient number of bulbs are thus cleansed, they are to be spread on a tin plate, and placed in an oven heated to the usual degree where they are to remain six or ten minutes, in which time they will have lost their milky whiteness, and acquired a transparency like horn, without any diminution of bulk. Being arrived at this state, they are to be removed, in order to dry and harden in the air which it will require several days to effect or by using a gentle heat, they may be finished in a few hours. By another process, the bulb is boiled in water freed from the skin, and afterwards suspended in the air to dry. It then gains the same appearance as the foreign salep, and does not grow moist or mouldy in wet weather, which those that have been barely dried by heat are liable to do. Reduced into powder they soften and dissolve in boiling water into a kind of mudlage which may be diluted for use with a large quantity of water or milk. Thus prepared, they possess very nutritious qualities and if not of the very same species as those brought from Turkey and used for making salep, they so nearly resemble them as to be held inferior. In Turkey the different species of the *Orchis* are said to be taken indifferently but in England, the *Orchis mascula* is the most common. (*Gloucestershire Report*, 571)

## CHAP. IX

### Marine Plants used in Agriculture.

6186. All marine plants may be used as manure with great advantage, either in a recent state or mixed with earth. It is used in this way more or less in all agricultural countries bordering on the sea, and in Britain in all those firths and estuaries, where, from the water not being at the maximum of saltiness, the plants which grow in it are not sufficiently charged with soda to render it worth while to burn them for the sake of the salt.

6187. The use of sea-weed, as an article from which kelp might be manufactured, seems to have been practically recognised in Scotland about the beginning of the eighteenth century. The great demand for kelp in the manufacture of glass and soap at Newcastle, and of alum at Whitby seems to have introduced the making of this commodity upon the shores of the Forth so early as about the year 1720. It began to be manufactured in the Orkney Islands in the year 1723, but in the western shires of Scotland the making of kelp was not known for many years after this date. The great progress of the bleaching of linen cloth in Ireland, first gave rise to the manufacture of kelp in that kingdom and from Ireland it was transferred to the Hebrides about the middle of the eighteenth century. On the shores of England the kelp plants are not abundant.

6188. All marine plants may be used for the manufacture of kelp, but the principal species in use on the British shores belong to the Laminæ genus *Fucus*. *Fucus vesiculosus* (fig. 815 a) is considered by kelp-makers as the most productive; and the kelp obtained is, in general, supposed to be of the best quality. *Fucus nodosus* (b) is considered to afford a kelp of equal value to that of the above species, though perhaps it is not quite so productive. *Fucus serratus* (c, or black weed, as it is commonly called, is neither so productive as the preceding, nor is the kelp procured from it so valuable. This weed is seldom employed alone for the manufacture of kelp; it is in general mixed with some of the other kinds. *Fucus digitatus* (*Laminaria digitata* H. B. 12, 543.) (d) is said to afford a kelp inferior in quality to that obtained from any of the others; it forms the principal part of the drift-weed.

6189. The plants are cut in May, June and July and exposed to the air on the ground till nearly dried, care being taken to prevent them, as much as possible from being exposed to the rain. They are then

turned in a bank out of kelp, formed by digging a pit in the sand, or by uniting a portion of the sand with kelp stems. On the bottom of this pit a post five is kindled, and the weed is gradually added, till

the fire extends over the whole floor; the weed is then spread lightly on the top, and added in successive portions. As it burns it leaves ashes, which accumulating towards evening become consolidated and are then well stirred. Another day's burning increases the mass, and this is continued till the kelp is nearly done. On some occasions the kelp consists of a cavity in the ground over which bars of iron are placed; and on this the ware is burned, the ashes falling into the cavity where they are well worked by the proper instruments.

6150. *Kelp is generally divided into two kinds: the cut-weed kelp, and the drift-weed kelp, the former made from the weed which has been recently cut from the rocks, the latter from that which has been drifted ashore. The latter is supposed to yield a kelp of inferior quality. Some specimens of kelp, however, made from cut-weed which had been drifted ashore tend to prove that this is not always the case. Weed which has been exposed to rain during the process of drying, affords a kelp of inferior quality. It is of the utmost importance to the manufacturer of kelp, to keep his weed as much as possible free from rain. For this purpose many employ sheds when these are not at hand, the weed which has been laid out to dry should be collected into one heap during the rain. When this ceases, it should again be immediately spread out. It has often been matter of dispute, how old the plants should be before they are cut; in general, three years is considered sufficient; thus, however, from some trials which have been made to ascertain this point, seems to be too long. From experiments, it appears, that the produce of kelp, from one two of three years' old weed, is only eight pounds more than that from the same quantity of two years' old. From this we would conclude, that the weed ought to be cut every two years. Though perhaps less weed may be procured from the same extent of ground occupied by weed of two, than of three years' growth, yet the difference may not be so great as to render it worth while to allow the weed to remain for three years.*

6151. *In order to increase the quantity of kelp, it has been suggested to the Highland Society that the seed of the *Salsola Soda* might be imported and cultivated at a small distance from the shore, with the design of sowing the plant with the sea-ware, for the improvement of the kelp. It was formerly imagined, that the barilla plant would not produce any quantity of alkali, worth its cultivation, if planted in France but in the year 1782, some spirited individuals procured a quantity of barilla seed, and made a plantation of it near the coast of the Mediterranean, in the province of Languedoc, and had the satisfaction for several years to find, that the barilla which they produced from these plants was of a quality equal to that which they usually procured from Alicant. Why then, may not a similar attempt in our own country be equally successful?*

6152. *Other plants. If the growers of kelp could contrive to make some considerable plantations of the most productive of the kali, or of sumitry wormwood, and other inland plants, which yield large quantities of potash, and collect the crop to burn with the other materials, the carbonate of potash resulting from their incineration would decompose the sea salt, and a great accumulation of carbonate of soda would be produced. It was proved long ago by Du Hamel, that the marine plants produced soda merely in consequence of their situation, for when they have been cultivated for some years in an inland spot they yield only potash.*

6153. *There are numerous tracts of shore on the mainland and islands of Scotland which may be easily cultivated for the production of kelp, from which at present not one penny is derived. All the cultivation requisite is, to place white or other hard stones, not under the size of the crown of a hat, upon such vacant spaces. Contractors have been made to plant stone lands in the Highlands with such stones, at the rate of 300 per acre or more. Such stones are generally to be found at high-water mark, on all the shores of the firths of the Highlands. They are put into a boat or high vessel, then carried to the ground to be planted, and thrown overboard; on the ebb of the tide they are distributed regularly over the shore, preserving a clear space of one foot round every stone, which distance, after very minute examination, appears to be the most eligible for producing the greatest crop of ware. It is evident these stones should be of a round shape; as the more surface that is exposed to the alternate action of the air and water so much more kelp will be produced than a given space of ground. In four years the first crop may be cut, which, on the shore stone will yield almost four per cent on the original expense. But the crop may be multiplied two kelp in every third year thereafter, which, on the same data, is equal to about five per cent. In this improvement there is no hazard of bad crops; and if the manufacture is begun early enough in the season, there is little danger to be apprehended from bad weather. It being understood that the operation of kelp-making must be carried on, should there be no more than two dry days in eight. (Highland Society's Trans. vol. v. and vi.)*

6154. *The cultivation of barilla (*Salsola Soda*, *Chenopodium*, a native of Spain), on a small scale, was tried in the gardens of Tynningham, the seat of the Earl of Haddington, in 1779, but without success, although planted under a south wall, in a most sheltered part of the garden. (J. M. in Gard. Mag.) The culture of this and other species is practiced to some extent in the neighbourhood of Alicant in Spain, and the details given*

in the *Cornus Comptis*; *Sp. mt. Soude*. The ground is brought into good till, and manured and the seed sown broadcast in October or November in the following spring the plants will be found an inch high and must be kept clear of weeds till the month of August, when, being at its full growth, it may be mown or pulled up (for it has scarcely any roots), dried, and afterwards burnt in holes in the ground like kelp.

8185 The sea-wrack grass (*Zostera maris Fluvialis*) is found in abundance on different parts of our own shores, as at Yarmouth the bays of the Orkney Islands, and other bays not exposed to the immediate fury of the ocean.

8186 It grows in banks of sand and mud, which banks appear to be held together principally by the roots of this plant, which are strong and succulent, and throw out numerous lateral fibres. It grows at such depths as to be left nearly dry by the ebbing of spring tides. During the autumn and beginning of winter these leaves are thrown on shore in large quantities. They are of a very imperishable nature, and may be kept for any length of time in fresh or salt water without any apparent decay. In the Orkney Islands this grass is thrown ashore during winter in large quantities, and collected by the inhabitants with other marine plants into heaps, for manure. In these heaps it is allowed to ferment, and sometimes, before being applied, it is mixed with earth or other matters. It is also used as thatch and forms a more durable defence against the violent winds and heavy rains of that climate than straw. A few years ago, in consequence of premiums offered by the Highland Society this grass was applied as a substitute for horse-hair and stalling mattresses and furniture. For this purpose it is carefully washed twice in fresh water then dried quickly, and afterwards, any sea-weed that had got mixed with it picked out. In the Orkneys it is steeped in fresh water takes for a week, then taken out and spread wet on the ground, and packed, while in this state, from extraneous matters. Exposure to drought for one day will make it sufficiently dry for packing. When dry care must be taken, if the weather is windy to gather it into heaps or cocks, otherwise it may be blown away being then extremely light. It is sent to market in large bags of soaking or twisted into ropes of the thickness of a man's waist, and then compactly made up in nets, formed of ropes made of bent grass. It is sold at the Asylum for the Indigent Blind at Edinburgh who employ it in stuffing mattresses. (Night See Trans. vol vi. p. 594)

# CHAPTER X.

## Weeds or Plants injurious to those cultivated in Agriculture.

6197 Every plant which appears where it is not wanted may be considered noxious, though some are much more so than others. A stalk of barley in a field of oats is a weed, relatively to the latter crop but a thistle is a weed in any crop, weeds, therefore, may be classed as relative and absolute.

6198 Relative weeds, or such cultivated plants as spring up where they are not wanted, give comparatively little trouble in extirpating them. The most noxious are the grasses when they spring up in fields or sown in or among corn crops in newly broken up grass lands. The roots of obnoxious plants that have been broken up after bearing that crop for some years, those of madder, liquorice, &c. are of difficult extirpation. When the potato crop has not been carefully gathered, or mustard has been allowed to shed its seed, they also occasion trouble. Other cases will readily occur to the practical man, and need not be mentioned.

6199 Absolute weeds, or such native plants as are considered injurious to all crops, are very numerous, and may be variously arranged. Some affect in a more peculiar manner corn-fields and tillage lands, and these are chiefly annuals, as wild mustard wild radish poppy blue bottle, cockle dandel, &c. or biennials, as the thistle or perennials, as couch grass, knot-grass, black couch, polygonum, &c. on lands laid down to grass for a few years, dock on eye-daisy ragweed, &c. Others infect grass lands, and these are chiefly perennials, such as crowfoot one of the most difficult of weeds to extirpate. Thistles, docks, rushes, sedges, reeds, and an endless variety of others. Some are more particularly abundant in hedges or where the reedy and coarse grasses, as couch grass, broom-grass the climbing and twining plants, as goose grass (*Oxalis Arvensis*) and the twining, as bind-weed (*Convolvulus*) are the most injurious.

6200 With regard to the destruction of weeds, they may be classed first according to their duration.

8201 All annuals and biennials as sand wort (*Sp. 816 a*) and sorrel *b*) are effectually destroyed by cutting over the plant at any point below that whence the seed leaves originated, as this prevents them from ever springing again from the roots. Perennials of the fibrous-rooted kind may be destroyed in the same manner as the crowfoot, ragweed, the fibrous-rooted grasses, and many others. Some fibrous-rooted perennials may also be destroyed by similar means but almost all the thick-rooted perennials require to be wholly eradicated.

8202 The perennials which require their roots to be wholly eradicated may be classed according to the kind of roots. The first we shall mention are the stoloniferous roots or surface shoots of plants, by which they propagate themselves. Of this kind are the creeping crowfoot, goosefoot or wild taraxacum, smartweed, strawberries, black neck grass, and most of the *Agrimonia* and other grasses. The next are the underground creeping roots, as the couch-grass, *Convolvulus arvensis*, and other species of bind-weed, coltsfoot (*Sp. 816 c*), and several tetradymous plants, as toadstool, Scrophularia, nettle hedge nettle (*Stachys lanuginosa*, *Sp. 816 d*), &c. Some of these, as the bind-weed and corn-bind, are extremely difficult to eradicate a single inch of stolon, if left in the ground, sending up a shoot and becoming a plant. The creeping and descending vivacious roots are the most difficult of all to eradicate. Of this class are the *Polygonum amphibium* (*Sp. 817 a*), the seed (*Arundo Perennis*), the hummock (*Sp. 817 b*), and some others. These plants abound in deep clay which have been denuded by water, as in the corns and clay vales of Scotland. In the *Larva* of Falkirk for example, the roots of the *Polygonum amphibium* are found

their proper names. Besides weeds which abound most, and are most injurious in one district, are often rare in another. Thus, the poppy abounds in gravelly districts, the charlock on clay, the chickweed, groundsel, *setula*, &c. only on rich soils. A local Flora, or any of the national Floras, as Lightfoot's *Flora Scitica*, and Smith's *British Flora*, and, we may be allowed to add, our own *Encyclopædia of Plants and Herbs Britannicus*, by pointing out the habits of indigenous plants, may be of considerable use to the agriculturist who has acquired a slight degree of the science of botany

## BOOK VII.

### THE ECONOMY OF LIVE STOCK AND THE DAIRY

6213 *The grand characteristic of modern British farming*, and that which constitutes its greatest excellence, is the union of the cultivation of live stock with that of vegetables. Formerly in this country and in most other countries, the growing of corn and the rearing of cattle and sheep constituted two distinct branches of farming, and it was a question among writers, as, according to Von Thuer, it still is in Germany, which was the most desirable branch to follow. The culture of roots and herbage crops at last led gradually to the milking or stall-feeding husbandry in imitation of the Flemings and afterwards, about the middle of the last century to the alternate husbandry which is entirely of British invention, and has been more effectually than any thing else the means of improving the agriculture of the districts where it is practised.

6214 *It is observed by Brown*, that "though horses, neat cattle, sheep, and swine are of equal importance to the British farmer with corn crops, yet we have few treatises concerning the animals, compared with the immense number that have been written on the management of arable land, or the crops produced upon it. But though so little has been written, the improvement of those animals has not been neglected—on the contrary it has been studied like a commerce, and carried into execution with the most sedulous attention and dexterity. We wish it could be stated, that one half of the care had been applied to the selecting and breeding of wheat and other grains which has been displayed in selecting and breeding the best proportioned and most kindly feeding sheep. A comparison cannot, however, be made with the slightest degree of success the exertions of the sheep-farmers having, in every point of view far exceeded what has been done by the renters of arable land. Even with cattle considerable improvement has taken place. With horses, those of the racing and hunting kind excepted, there has not been correspondent improvement and as to swine, an animal of great benefit to the farmer, in consuming offal which would otherwise be of no value it is to be regretted that very much remains to be done."

6215 *The first important effort in the improvement of live stock* was made by Robert Bakewell who was born on his father's estate of Dishley, in 1725. Mr Bakewell wrote nothing himself, so the first scientific work on the subject was written by George Cullery in 1782, who had formed himself on Bakewell's model. The systematic improvements of Mr Bakewell were developed in various agricultural reports, and contained in attempts to lessen such parts of the animal frame of cattle and sheep as were least useful to man as bone, cellular substance, and appendages at the same time increasing such other parts, as flesh or muscle, and fat, as became more important in the furnishing man with food. These ends he endeavoured to accomplish by a judicious selection of individuals, possessing the wished-for form and qualities in the greatest degree which being perpetuated in their progeny in various properties, and the selection being continued from the most approved specimens among those, enabled him at length to establish breeds with the desired properties. Later improvements have been grafted on these, and we find excellent observations on the subject from the pens of Cline, Dr Coventry Sir J. Sebright, Hunt of Leicester, and the Rev H. Berry and we have witnessed the strenuous and successful efforts of a Russell, a Coke, an Elliman, and others. The improvement in the sciences of comparative anatomy and physiology has also led to an amended practice both in breeding and in pathology. The example of various excellent proprietors and farmers in all parts of the empire tended to spread this improvement, by which the pursuit became fashionable. Add to these the accounts of the management of live stock in almost every county of the British Isles, as contained in Marshall's *Worls* and the *County Reports*. From these sources we shall draw the information we are about to submit, and shall adopt the arrangement of the horse, the ass, the mule and hinny the bull family and the dairy the sheep, the swine, miscellaneous stock, and various animals or vermin.

## CHAP. I.

*The cultivated Horse.*—*Equus Caballus* L. *Mammudus Bēlus* L. and *Pachydermus Indipeder* Cuvier. *Cheval*, Fr., *Pferd*, Ger. *Cavallo*, Ital., and *Caballo*, Span.

6216 *The horse family*, by far the most important among the brute creation as a servant to man, includes several species both in a wild and cultivated state, as the *Equus Hemionus*, or wild mule, a native of Arabia and China, and which it is supposed would form an excellent race of small horses, could they be reduced to a state of domestication; the *E. Asinus*, or ass, well known, the *E. Zebra*, or striped ass, the *E. Quagga*, by some considered a variety of the zebra; and the *E. badius*, or cloven-footed horse, a native of Chile, and by many supposed to belong to a distinct genus.

5217 The common horse, justly considered as the *vulgaris quadrupes*, is found in a wild state in the deserts of Great Tartary, in the southern parts of Siberia, and in other parts of Asia, and in the interior of Africa. He has long been domesticated and cultivated in most parts of the world, for the various purposes of war, hunting, parade, the saddle, and draught; and in some places, partly for his flesh and the milk of the female. The parts of a horse, when no longer endowed with life are applied to various useful purposes. The blood is used as manure. The bones are broken and boiled, to produce oil and are afterwards ground into an excellent manure. Some of the bones are also employed in the mechanical arts. The flesh supplies food for the domestic carnivorous animals, the cat and dog, for carnivorous birds, kept for amusement or curiosity for fish &c. We shall consider the horse in regard to its varieties, organology, anatomy, physiology, diseases, breeding, rearing, training, feeding, and working.

#### SECT. I. Varieties of the Horse.

5218. The varieties of the domestic horse are numerous. The indigenous horse of every country, operated on by climate, assumes that form best adapted to its locality. Man would soon, however, be led to mix with the native breeds that variety which presented in its aboriginal state the finest form and most valuable qualifications. This being found contrary in the horses of Arabia, Persia, and Barbary the inhabitants of Europe generally sought an amelioration of their own breeds by an admixture of oriental blood.

moderate size; but strong, muscular, full of spirit, and active. The Tartars are considered skilful riders. Like the Kalushka, they eat the flesh of horses as we do that of oxen, and use their milk either in curd or fermented.

5220. Of the European varieties of the horse, those of Italy were formerly in greater esteem than at present but still those of the Neapolitans shine both under the saddle and in traces. Great numbers are bred in Sicily those of Sardinia and Corsica are small, but active and spirited. The Swiss horses partake of the same qualities.

5221. The Spanish horses have long been highly esteemed. The invasion of the Moors, in 710 brought a vast influx of oriental blood into Spain and the continuance of the Moorish yoke during several centuries produced altogether so improved a race there, that the best Spanish horses are preferred by some to the Arabs. The Spanish Gemito has long been celebrated for its elegance, sprightliness, and durability. The best breeds of Spain are generally finely carcassed, and well limbed, active, ready, and easy in their paces, docile and subservient to their owners, full of spirit and courage, but tempered with mildness and good-nature; they are, for the most part, of a moderate size. Those which are bred in Upper Andalusia are deemed the most valuable. The Portuguese horses, or rather mares, were famous of old for being very fleet and long-winded; but of late it is said, they are much degenerated.

5222. France abounds in horses of all kinds, whose origin may be traced to a mixture of their native breeds with the Asiatic introduced by the invasion of the Goths and originally received from the Byzantines, and the true eastern blood reserved from Spain, Barbary and Arabia. With these admixtures, however, the horses of France have not yet borne a high character throughout Europe and although under the dominion of Napoleon more than two hundred pure Arabian stallions were imported, and the northern states plundered of their choicest specimens by which the breeds have been much improved still France imports yearly vast numbers from this country particularly hunters and high bred carriage horses. Of their own horses, Languedoc furnishes some good saddle horses, and hunters also. Next to those, Normandy claims precedence for a well-formed and useful breed. There are also very good *old* *de* *Normandie* horses in Auvergne, Flanders, and Burgundy. Lower Normandy and the district of Cotentin furnish some very tolerable coach horses, and which are more active and appear more elastic in their motions than the Dutch horses. They have, however, a noble race of large draught horses equal to any seen in England, and among which the chestnut colour seems to prevail. The French horses generally are apt to have their shoulders although oblique, yet too loose and open, as those of the Arabs are usually so compact and square.

5223. The Flemish horses are inferior in value to the Dutch, having usually large heavy heads and necks; their feet also are excessively large and flat, and their legs subject to many humors and swellings.

5224. Holland furnishes a race of horses which are principally serviceable in light draught work the best ones, being Friesians.

5225. Germany is not destitute of good horses. The native breeds, heavy and ill-formed, received their first improvement from admixture with the Asiatic horses. In after-times the Germans obtained still

of one brought by Buonaparte from Egypt, and now living in the royal garden of Paris, are reckoned the best, and the solicitude with which the Arabs preserve these horses pure and unmixed is remarkable. The care with which they are nurtured, and the skill displayed in their equestrian management, are no less admirable. None but stallions of the finest form and purest blood are allowed access to their mares, which is never permitted but in the presence of a professional witness or public officer who attests the fact, records the name, and signs the pedigree of each. The Persian horses are considered next in value, and after them the horses of Andalusia in Spain. The Barbary horses are descended from the Arabians, and much esteemed. Jackson (*Empire of Morocco*, p. 46) mentions one very fleet variety used for hunting the antelope, and fed entirely on camel's milk. The horses of India, though active and not ill formed are small and vicious, the climate being unfavourable to their greater development. Those of Tartary are of a

their steeds from the Arabs, Turks, and the Barbary states, which they still preserve with some care, as statements of good specimens are also obtained from Spain. In a general point of view, however, the German horses are those fitted for the carriage than for racing or hunting, in which qualities they are inferior to the Hungarian and Transylvanian horses. The horses of Bohemia are not distinguished by any eminent qualities. The Huns and Transylvanians are accustomed to sit the nostrils of their horses, under a notion of giving their breath a free passage, and improving their wind, as well as to render them incapable of neighing, which in the field, would be often inconvenient. The Croatian horses are nearly allied in qualities and character to the Hungarian and Bohemian ones, as well as the Poles, are remarkable for being, as the French term it, *bigot*, or keeping the mark in their teeth as long as they live.

6226 The Polish horses are hardy, strong, and useful, but they are generally of a middling size. In the marshy parts of Prussia, and towards the mouth of the Vistula, there is a breed of tall strong horses, resembling those of Friesland, but of inferior value.

6227 The horses of Russia are not much regarded by other nations. They are small but hardy and capable of enduring great fatigue. Great attention is, however, paid to such as are very fast in their trot, and such a breed is much encouraged for trotting matches on the snow and ice. Those of the Turkish breed are handsome and finely shaped, but too slight and weak for heavy cavalry. The Mahometan horses are somewhat higher than the Russian common horses, and are so lasting and constitutionally strong as to be able to run three or four hundred English miles in three days. They sweat, summer and winter, solely upon grass in the great deserts which are between the river Don, Volga, and Vank where they are collected in great herds of four hundred, five hundred, or even a thousand. They are excellent swimmers, and pass the river Volga where it is from one mile to two miles broad, with great ease.

6228 The horses of Sweden are low and small, and the Norway breed may be comprehended under the same description, but they are strong, hardy and active. Denmark and also Holstein and Oldenburg, boast a large variety of horses, which has long been esteemed as peculiarly adapted for heavy cavalry and carriage uses, though they are not so full with respect to elegance of form and symmetry of parts, their heads being large, their shoulders heavy, their backs long, with croups too narrow to correspond with their fore parts. In the islands of Leroe there is a race of horses of small growth, but strong, speedy and very sure footed. They are never shod and feed abroad without shelter both summer and winter. In Sweden, one of these islands, they have a peculiarly swift breed of grant use to the inhabitants, who catch their sheep, which are wild by hunting them with a dog, pursuing them at the same time with their horses. The horses of L. land are small of stature, but active and willing; they are used only in the winter season in drawing sledges over the snow and transporting wood, forage, and other necessaries, but in summer they are turned into the forests, where they form separate troops, strictly confined to their own quarters.

6229 The British varieties of saddle horse may be reduced to the racer, the hunter, the improved hack, the old English road horse, the gallopway, and the pony, the two latter of which we shall consider in another place.

819

6230 The race horse (fig 819) is descended nearly in a direct line from the Arabian, the Persian and the Barb. In an agricultural point of view, this celebrated breed might at first sight appear of little importance, but it is probable, that to the amusement afforded by it to the rich and powerful, we are indebted for the principal improvements in every other variety of this most valuable animal. Races or courses were very early a part of British sports, and it is natural to suppose that, on this account, endeavours would be made to improve and enlarge the breeds of the native horses. Roger de Belleme, Earl of Shrewsbury is the first sovereign who imported a Spanish stallion, the progeny of which was afterwards extolled by Michael Drayton in his *Polyolbion*; and, it is probable, the first amelioration of the native breeds was derived altogether from horses brought from Spain and the southern parts of Gaul. In the reign of Henry IV. public ordinances were made favourable to the improvement of the breeding of horses, which would tend still further to extend the search after better specimens. There is reason, however, to believe, that the courses of those times were little more than ordinary trials of speed between the natives, or those slightly improved breeds, and it was not until the days of Henry VII. and VIII. that the true western blood was collected in any considerable quantities. During these reigns, however, it becoming very general to import stallions from Arabia, Barbary and Persia, a new and highly improved race rapidly extended itself. This improvement was carried subsequently to its acme by an equally careful selection of mares as of horses, and thus we find King James reporting a set of mares of the purest blood, significantly called the royal mares. From these periods, the breeding of the race horse was pursued with the utmost care, as well in regard to purity of blood as in the increase of his bodily powers, by the most nutritious food and duly apportioned exercise, during his training for the courses, then becoming so fashionable in England. Thus has been produced a breed unrivalled throughout the world for symmetry of form, swiftness of progression and durability under exertion. The accounts on record of feats performed by some of our horses on the turf are truly astonishing. Bay Malton ran at York four miles in seven minutes and forty-three seconds. Children, known by the name of the Flying Children, moved through a space equal to eighty-two feet and a half in a second. After these Eclipse, Highflyer, Matchem, Hambletonian, and others, have contributed to keep up the reputation of the English races.

6231 Climate has a great influence over the form of animals, and that form is found indigenous to each which best fits it for the purposes required of it. In the arid plains of the east, where herbage is scarce, a form is given which enables its brute inhabitants to readily transport themselves from one spot to another, and as in every situation the flesh of the horse is greedily sought after by the predatory tribes, so here, where there are peculiarly strong and active, the horse is formed peculiarly agile and swift to escape their attack, as well as peculiarly light, that his weight might not sink him in the sandy plains, nor his bulk retard him in his flight. Removed, however, to more temperate climes where vegetation affords by its luxuriance more nutriment, and where the restrictions of danger have ceased to operate, we no longer see him equally small and slender, but, with equal capacity for swift progression, we find him extended into a form capable of keeping up that progression with a durability unknown to the original breeds from which he sprang. Symmetrically formed as we now see him, he at once assumes his claim to great speed. His bony skeleton exhibits a line founded on the highest geometrical principles, presenting a series of lengthened levers acting by means of a condensed muscular and tendinous organisation of great power on angles capable of great flexion and extension; while his jointed form fits him to elude that atmosphere, from which his deep chest enables him to draw by extensive inspirations wind and vapour to condense his exertions. Purity of blood by which is meant the result of continuing to particular races of

breeds that object of distinguishing their quality, is observed with equal care and judgment by the breeders of the English race, as by the Arabians; and their jealousy leads them to discover a mark of degeneracy from the purity to the uttermost remedy.

820. The *Andalus* (Ag. 820) is derived from horses of active blood, or such as are but little removed from it, meeting with means of substance, correct form, and good action. In some instances however are derived from large masses of the pure breed, proceeding with powerful stallions of the old English road horse.

This Andalus and valuable breed is a happy combination of the speed of the Arabian, with the docility of the native horse. More esteemed in Spain, but famed on the same principles, he is able to carry a considerable weight through heavy grounds, with a swiftness equalled only by the animal he pursues, and with a perseverance astonishing to the natives of every other country. Hence the extreme demand for this breed of horses in every European country, our racing stallions being now sent to propagate in the eastern climate, whence they were some of them originally brought.

821. The improved *Andalus* (Ag. 821) is derived, like the former from a judicious mixture of the blood breed with the native horse, but exhibiting a greater proportion of the latter. Hackneys are now however mostly bred from stallions possessing nearly the same proportion of blood with the Andalus, but with a form and qualities somewhat different. Is the hackney as safety as we require as speed, we look particularly to the fore parts to see that they are high and well placed that the head is not heavy nor the neck disproportionately long or short; that the legs stand straight (that is, that a perpendicular line drawn from the point of the shoulder should meet the toe) and that the elbows turn out and although a perfect conformation in the hinder parts is necessary to the hackney, it is in some measure subordinate to the same perfection in the fore parts, whereas in the mace and hunter but particularly in the former, the form of the hinder is even of more consequence than that of the fore parts.

822. The old English road horse. This most useful breed is now nearly extinct, although some northern agriculturists appear to be making efforts to revive the race. It has so long been known to this country that it although it is probable that it originally sprung from a Persian extraction, which horses were very early imported to enlarge our small breeds, and to render them equal to the heavy loads they were accustomed to carry as pack-horses and of which kind the old English road horse unquestionably is. (Ag. 822.) Neither is it at all impossible, that, in the more fertile parts of the island, an original breed existed of considerable power and bulk. Athelstan expressly prohibited the exportation of English horses, and the "scythed chariots drawn by fiery steeds" of the ancient Britons struck terror into Caesar's legions. These accounts of the antiquity of the English horse, receive additional strength from the notices we obtain of the fossil bones of horses having been found, according to Parkinson, in various parts of the island. The old English road horse possessed great power, with short joints, a moderate shoulder elevated crest, with legs and feet almost invariably good. The heights varied from fifteen hands to sixteen hands two inches and the colours were frequently mixed.

823. The *Andalus*, *Andalus* to English ears, both of the original and of the more early improved breeds, and which is even still seen among them, is, that they want grace or expression in their figure and carriage; that they are somewhat obstinate and sullen and that a certain stiffness in their shoulders, and want of suppleness and elasticity in their limbs, render them unfit for the carriage. As this is an important objection against the excellence of our breeds, it may be worth consideration how far it is founded in truth. Commerce requires despatch, and England as a great commercial country makes every thing subservient to an economical use of time. Conformably to these principles, many of the qualities of our horses, but principally those of docility and safety in progression, are carefully sacrificed to speed, in which they undoubtedly excel all horses in the world. It is well known that all animals intended by nature for quick progression, are formed low in their fore parts, and have usually narrow upright shoulders, which defects are too common in English horses in general. On the contrary, in most of the improved breeds of continental horses, the fore hands are elevated, and the shoulders wide and oblique by which, facility and safety in progression are gained at some expense of celerity. For the strong hinder muscles of horses as formed, resting on the lengthened spinous processes of the dorsal vertebrae with increased advantage, elevate the fore parts higher and even in default of this form in the fore parts, yet a corresponding effect is produced in foreign horses by the great strength and expansion of their hinders and croup. And by the greater impulsion in their hinder extremities towards the common centre of gravity of the body; for in speed depends first on the extent to which the region of the hinders can be stretched and secondly, on the extent of the body in the direction to counteract the tendency in the common centre of gravity, the earth; so it is evident that the form which is the most favourable to speed is less of an enemy or perfectly in progression.

824. The *Andalus* road horse, or *Andalus*, equal with, or probably in some measure subjugated to, the culture of the old English road horse, was a still more excellent breed. With similar proportions, but an improved form, with a greater acquired aptitude for turning, it gained the name of the Irish hunter; and when the age of the horse was less speedy than that now are, this horse was equal to carry things required of him as a hunter, even now the possession of the few which remain find, particularly in an ancient and deep country, that what others gain by speed these accomplish by strength as

Side and fore, back long and straight, but always very straight, sides flat, shoulders too far forward, hind

825

825. The Clydesdale horse (fig. 825.) has been long in high repute in Scotland and the north of England

826

and usually black, with wide heels the back straight and broad, but not too long the hocks roundish, but not prominent, and the space between them and the ribs short, the tail heavy and well haired, the thighs meeting each other so near as to leave only a small groove for the tail to rest on. One most valuable property of this breed is, that they are remarkably true pullers, a native horse being rarely found among others.

826. The Welsh horse (fig. 826.) bears a near resemblance, in point of size and habitness, to the best of

827

the native breed of the highlands of Scotland, and other hilly countries in the north of Europe. It is too small for the present two-horse ploughs, but few horses are equal to them for enduring fatigue on the road. "I well remember," says Culley "one that I rode for many years, which, to the last, would have gone upon a pavement by choice, in preference to a softer road." (*Observations on Live Stock*, p. 35.)

827. The galloway (8), properly so called as being found chiefly in that province of Scotland, has now become very rare, the breed having been neglected from its unsuitableness for agricultural purposes. Galloway is, however, used as a term for any horse between the pony size and the hack, and in this point of view is sufficiently common, and very extensively used by small farmers on commons and wastes. The true galloway is somewhat larger than the Welsh horse, and is said to resemble the Spanish horses there is almost everywhere, that some of the latter, that had escaped from one of the vessels of the Armada, landed on the coast of Galloway, were allowed to intermix with the native race. Such of this breed as have been preserved in any degree of purity are of a light bay or brown colour with black legs, and are easily distinguished by the smallness of their head and neck, and the closeness of their hair.

828. The still smaller horses of the highlands and isles of Scotland, (c) are distinguished from larger breeds by the several applications of points, whiskers, and in classic at garrows or garrows. They are found in great numbers in the Highlands, or western parts, where they are found in the greatest variety. Different varieties of the same race are spread over all the Highland districts, and the northern isles. This ancient breed is supposed to have been introduced into Scotland from Scandinavia, where the Norwegians and Danes first obtained a footing in these parts. "It is probably the same breed that exists at present in Norway, the Feroe Isles, and Iceland, and is totally distinct from every thing of horse kind in the continent of Europe, north of the Baltic. In consideration of this, there is one peculiar variety of the horse in the Highlands, that deserves to be noticed, it is termed the out-land horse. He is of different colours, light bay, dun, and sometimes cream-coloured, but has always a blackish tint that runs along the edge of the back, from the shoulder to the rump, which has a

resembling to an old stretched out. This very singular character subsists also in many of the horses of Norway and is nowhere else known" (*Writer's Memoirs*, vol. ii. p. 182). "The Highland horse is sometimes only nine, and seldom twelve hands high, except in some of the southern of the Hebrides, where the size has been raised to thirteen or fourteen hands by selection and better feeding. The best of this breed are handsomely shaped, have small legs, large manes, little neat heads, and are extremely active and hardy. The common colours are grey, bay and black; the last is the favourite one." (*General Report of Scotland*, vol. iii. p. 1/6.)

## SECT. II. Organology or exterior Anatomy of the Horse.

6247 *A just knowledge of the exterior conformation of the horse* to be able to form a correct judgment on the relative qualities of the animal forms the *ne plus ultra* of a scientific horseman's aim, but it is a branch of knowledge not to be obtained without much study and experience. In considering a horse exteriorly his age, his condition, and other circumstances should be taken into the account without which attention it is not possible to determine, with precision the present or future state of a horse when he is seen under various peculiarities. A horse of five years old though considered as full grown, yet experiences very considerable alterations of form after that period. He then becomes what is termed *furnished*; and all his points (i. e. his adult form), before hidden in the plumpness of youth or disguised by extreme obesity now show themselves. From the effects of muscular exertion promoting absorption, he becomes more angular and to the painter's eye, would prove more picturesque, but less beautiful. A horse likewise low in flesh and condition is hardly the same animal as one in full flesh and condition and again the sleekness acquired from relaxed labour with full and gross feeding is very unlike the robust form acquired from generous diet with correspondent exertion.

6248 *The examination of the subject of organology* is conveniently pursued by dividing it into head, neck, trunk or body and extremities or legs. The greater number of well proportioned horses, with the exception of the head and neck, come within a quadrangle not one strictly equilateral as depicted by Lawrence (Richard) and Clark but one whose horizontal dimensions are usually between a twenty fourth and twenty-eighth greater than their perpendiculars. It must, however be kept in mind, that with some considerable deviations from this quadrangular form many horses have proved superiorly gifted in their powers and that a deviation from these proportions appears in some instances, as in that of the race horse not only favourable, but necessary also to his exertions. Nature will not be limited and the perfection of her operations is not alone dependent on the arbitrary arrangement of parts, but on a harmony and accordance of the whole, internal as well as external. To the artist, however, such admeasurement is useful inasmuch as it prevents any singular departure from a symmetrical appearance which is but too common among our animal draughtsmen. To the amateur it also offers a convenient, though not an unerring guide. Our exemplification of the organology appears by placing a blood and a cart horse within the same square (fig. 828.) by which the differences between the various parts of the one and the other are readily contrasted.

6249. *The organs of the head.* The head of the horse is remarkable for its dimensions, formed by an elongation of the jaws yet in him as in most of the grazing tribes, its bulk is in an inverse proportion to the length of the neck, otherwise the muscles would not be able to lift it. It is an important part considered as relative to beauty alone, it being in the inferior heavy breeds but little marked by grace or expression but in the improved varieties it presents lines worthy the painter's pencil and the poet's fancy. Neither is it too much to say that in no part of the body is this amelioration of breed so soon detected as in the head. Can any thing be conceived more dissimilar than the small inexpressive features of the cart horse and the bold striking ones that grace the head of the blood horse? The quick succession of movements in his pointed ears, the dilatations of his expanded nostrils, or his retroverted eyes, which give fire and animation to the character of his head when under the influence of any excitement. This is the more worthy of remark, when it is considered that some of the principal aids to expression in the human countenance are wanting in the horse. Man borrows much of his facial expression from his eyebrows, and when to these the varied action of the mouth is added, it amounts to more than a half of the total expression. A great accession of beauty is gained in the improved breeds by the increase of the facial angle, which in them is about  $25^\circ$ , but in the heavy breeds is usually only  $23^\circ$  (see 828.)

828. *The ears* (A B) in the improved breeds are small and pointed. In the heavy they are not only large and ill shaped, but they frequently separate from each other these defects gave rise to the barbarous custom of cropping now happily in a great measure abolished. The ears are organs of the spirit, as well as of the temper; we have seldom seen a horse which carried one ear forward and the other backward during his work that was not hardy and lasting. Being not subject to early fatigue, he is attentive in every thing around him, and directs his ears different ways to collect sound from every quarter. The ears are also indications of temper and a horse is seldom either playful or vicious but his ears are laid flat on the neck, it is fortunate that we are provided with such a warning, by an animal that does not want craft to deceive us, nor strength to render his resentment terrible.

552. The forehead part presents itself to *c*, straight, and of a proper width in the improved breeds, supported by nature with an oblique surface of hair, which, detaching itself from the rest of the mane, flows down the face to protect both that and the ears from the attacks of insects.

553. The eyes (*d d*) deserve particular attention, not only for their utility but as objects of beauty and expression. In the blood horse the orbicary fossa, or eye-sockets, are more prominent and more inclined by which the axes of his eyes diverge more from each other than those of the heavy breed by which not only he is enabled to see further behind him, but the prominence of his eyes gives great beauty and expression to the blood horse. The further consideration of the eyes, and their criteria of soundness, will be postponed to the anatomical detail, in old horses most of the fit of the body which is more superficially placed in the young, becomes absorbed; as the way the eye, which is usually embedded in a vast quantity of this matter losing its substance, sinks within its orbits, and thus the cavities above, called eye-pits, show themselves deeply in an aged horse.

554. From the core to the angle of the jaws (*e e*) large vessels and extensive glands are situated. Within these branches of the posterior jaw is lodged the throat, and it will be observed how necessary it is that these branches should expand sufficiently to admit of the motions of the head, particularly of those influenced by the raising-in of the bridle otherwise the blood-vessels and other parts must be injuriously pressed upon.

555. The hollow between the jaws is called the channel, and at the under part of it (*f*) a considerable branch of an artery proceeds from the inner side over and around the outer which branch forms the most convenient situation for feeling the pulse of the horse.

556. The face (*g*) of the improved breed of horses presents either a straight line, or one slightly curved forward towards the lower part whereas, in the heavy breeds, it is very commonly found to be curved outward. This part comprises, as with man, from the forehead to the lip. When the face is covered with white, it is considered a bluish; but when a white spot only exists in the forehead, it is considered a beauty.

557. The markings on the face are useful to describe a horse by, and frequently lead to the recovery of a strayed or stolen one. In regimental accounts these marks are carefully noted. When a spot extends down the face, it is termed a blaze and when further continued into the muzzle, it is called blaze and snout. When a star is distinct, but with it there are white markings which begin some distance below it, and run continued downwards, it is called a vulva.

558. The muzzle (*h h*) includes the lip, mouth, and nostrils; the darker the colour of this part the more is the horse esteemed. Very dark brown horses are an exception, for in them it is usually of a tan colour, and is prized both as a beauty and indicative of excellence. It is both a beauty and an excellence that the muzzle be thin, angular, and large.

559. The jaw should be wide, firm, and by no means soon and pendulous, as is the case in the old and straggled. The jaw in the horse are the principal organs of touch and discrimination, and hence are necessarily sensible.

560. The form of the mouth, as reaching the bit, is important. It is also of more consequence than is usually supposed, that its circumference or opening be sufficiently deep; when shallow, it is not only inconvenient, but it will not admit a bridle thoroughly into its proper resting place upon the bars. Within the mouth are situated the teeth, which are so placed as to have interrupted portions of jaw above and below of considerable extent. These portions are called bars, and are parts of extreme importance to the horseman, as it is by means of spurs which bite within on these parts, and according to their condition by means of a trace, the lower part of which is to the head of the rider that he secures obedience. In old and straggled horses, to each portion of this lower is attached a skin, called a curb, which acting on the outer part of the curb, increases the pressure. This latter part has been called the curb or beard, but its situation is evidently above that.

6260. The teeth (fig. 622), which present themselves on the lower parts of the jaws, are the incisive and canine. The two front incisives are particularly marked as upper and lower (a); the two next adjoining, separators or middle teeth (b); and the outer the canines (c) but it would be more definite in any the first, second, and third incisives, beginning at the corner. The canine or tusks (d) occupy part of the intermediate space between the incisive and grinding teeth. The teeth as criteria of age, will be considered in another place, and as organs of mastication, they will be further noticed in the anatomical detail.

6261. The organs of the neck. The exterior parts which compose the neck are first the upper surface, which is furnished throughout its whole extent with an elegant covering of hair called mane (fig. 623 a c). In some instances as in stallions, it is of enormous length and thickness. In dark-coloured horses it is commonly black, but in horses of colour approaching to a light hue the reverse is frequently seen, and the mane and tail are in these often lighter than the body.

6262. To make the hairs of the mane and tail for smooth is an object with most horsemen but the pulling the hair out in tufts by wrapping it round the fingers is a most erroneous practice, and not only at the time frustrates the end intended, but a mane so pulled will seldom hang well after. The writer of this has always made use of a three pronged angular mane-puller which, if used two or three times a week, will bring both mane and tail into perfect order, and will keep them so. This iron is manufactured and sold by Long, veterinary instrument maker in Holborn, London.

6263. The upper surface of the neck (d) should form a moderate but elegant curve, which is greatly favourable to beauty. This curve is, however, not so considerable in the pure eastern variety as in the better sort of northern horse.

6264. The under surface of the neck (e h) should be nearly straight. In the cool-blooded horse it arches outwards, and the upper surface in some instances is sometimes hollowed upwards in equal proportions, when such horse is called ewe-necked. When this deformity is considerable, it prevents the head from being carried in its true angle, and particularly so under the action of the bridle, in which case the nose being projected forwards, carries the axis of the eyes upwards: such horses are called star-gazers and it is to be observed that they are seldom safe goers. In mares and geldings a very just criterion of a sluggish disposition, may be formed from the presence of a considerable quantity of flesh on the upper surface of the neck when the crest is very thick and heavy it is almost an unerring prognostic of a head sluggish. In stallions it, however, forms a distinctive sexual mark, and therefore is less to be depended upon in them. In a well-proportioned horse the length of the neck, the length of the head, and of the angle joining the two, should give the height of the withers from the ground. When the neck is too long, the head must of course gravitate by the increased length of the arm of the balance, it likewise seldom presents a firm or proper resistance to the bridle. When, on the contrary the neck is too short, the head is frequently ill placed, and the lever in the hand of the rider will be too short also.

6265. The organs of the trunk or carcass are various. Considered as a whole Clark has not unaptly likened it, when separated from the limbs, to a boat within which are disposed various important viscera. The bony ribs he likens to the wooden ones encompassing the vessel, and the sternum or breast-bone, being perpendicularly deep and thin, carries the resemblance further and fits the machine to cleave the air as the boat does the water. Within this animal vessel according with the just mechanical principles, the weightiest of the viscera, the liver, is placed in the centre, and the others follow nearly in the relative order of their gravity so that the lungs, the lightest of the whole, are stowed in front, where great weight would have been most disadvantageous.

6266. The shoulders (a e, h h) are commonly considered as extending from the withers above to the point in front, and to the line behind formed from the elbow upwards but a correct description considers them as those parts immediately concerned in motion. That is, the scapula or blade-bone, and its attachments. The shoulders are too apt to be confounded with the withers above, and with the arm below erroneously called the point of the shoulders. From this confusion great error is committed in appraising their nature and action but this is removed by recourse to the skeleton (fig. 53 c b d). The withers (c d) may be justly proportioned at the same time that the shoulders may be narrow straight, and altogether badly formed, and vice versa. The shoulders should be muscular and narrow but not heavy, and to determine between these essential points, requires the eye of experience in the viewer and the presence of conditum in the viewed. A muscular shoulder is essentially necessary, when we consider that the fore extremities are wholly connected by muscle, and not as in man, by the intervention of the bony union of the clavicle or collar bone. In the horse, therefore we find that large muscular masses unite the shoulder blade, by its upper and inner surfaces, to the chest while other powerful muscles suspend as it were the machine between them. By this contrivance, elasticity is preserved and strength gained, for had the shoulders possessed a bony connection, when the body is propelled forwards, its weight and force being received by the fore extremities, painful and hurtful shocks would have been experienced at every step. Powerful muscles for the shoulders are also as necessary for progression as for attachment. It is not therefore with judgment that a very thin meagre shoulder is commonly preferred. It is by the union of strength with just proportions, and a proper situation of the parts, that the value of the animal is determined.

6267. The centre of action in the shoulder (c) is in their common centre, and the extent of action of any part moving on its centre, is dependent on the length of such part the motion the shoulder enjoys is confined to the perpendicular backwards, and to as great an elevation of the muscles as they will admit of forwards. It will be therefore evident that the more oblique is the situation of the shoulder blade, the greater number of degrees it can go through. It must be as evident also that when the shoulder blade is long and deep, as well as oblique, that this advantage is increased. It is commonly observed, although it is not invariably the case, that when the shoulder is short, it is also upright (h h). Obliquity and length in the shoulder favour the safety of the progression also for as the angles formed between the shoulder the arm, and fore-arm, are consecutive, and make when in action, a bony arch as the obliquity and length of the shoulder is favourable to a due elevation of the limb, on which, in a great degree, depends the safety of progression. Thus mares are, *ceteris paribus*, more unsafe than horses, their shoulder being short to correspond with the low mare-like forehead and their decreased obliquity usually requires an increased obliquity in the whole limb downwards, or as is familiarly expressed, they stand with their legs under them. Unfavourable as is the form of the mare, both for the speed and safety of their action, it was given for advantageous purposes for by such a position in the fore extremities, the hinder are raised higher to afford additional security against the evils of gravitation and displacement of the feet from the pelvis. Few rules can be laid down in the exterior conformation that require so important, or of such general application, as that a short and upright shoulder, particularly when united with an

indeed direction of the whole thus backwards, is a not infrequently of a slow and slow. It now and then is a sure mark of an unsafe gait and commonly, though more rarely and good moves, which would appear to be a sign of a defect in the hind legs, but it will be found that, whenever horses having these defects in their feet, to counteract these principles, but it will be found, invariably have hinder parts of great strength and legs yet prove quick and safe in progression, they appear possible, that the hind and fore parts do not bear proportion to make up the deficiency. Indeed, it is in blood horses, the withers are not always high, and still the same relative proportion in all horses alike, oblique, yet the fore limbs are altogether short in proportion, though their shoulders are commonly deep and flexible frame. For, as speed appears to be a principal end in all we do to the hinder in a great number of the animals as with abundant proof that all animals destined to make any formation, and as comparative anatomy is nothing more than a succession of leaps are low before, the considerable leaps (and the full gallop answered by the arrangement of parts; it is also more than probable, and of their formation is really best may be found with a defective forehand, yet, in the slower paces of this that, although speed in the gallop formed shoulder is more immediately regulated. This subject will be still further carried out, and walk a justly her elucidated when we treat on the mechanical properties of the skeleton.

6268. The *withers* (*e*) are formed by the long transverse processes of the thoracic vertebrae (*fig* 6267, *p*), and as their use is to serve as levers to muscles, so their length characterized by the *height of the withers* (*fig* 6267, *p*), must be of great advantage, and enable such horses to go high above their ground. For, height of the withers back, acting to greater advantage, elevate the fore parts more forcibly. From this we may also learn that the elevation of the fore parts, or the horse's going above his ground, as elevated action is, they also learn that not altogether dependent on the motion of the shoulders, nor on the height to which the animal is raised, is not inclined to lift merely his legs. But likewise, on the extent to which the fore half of the neck is raised, may be either elevated by the action of the dorsal and lumbar muscles. When the withers are high, the animal may be hand well up, as it is termed, it is favourable to the celerity and to the safety of the action, but in the fore- properties are less wanting in the heavy breeds, we find in them a considerable variation of form, as those cast horse, weight of forehand is an essential requisite to his exertions, for drawing being an effort in the animal to preserve himself from the tendency which his weight gives him to the centre of gravity. The neck is inclined forward, so the more weighty and bulky he is before, and the nearer he approximates to the centre, the more advantageously he will apply his powers. It is not here intended to be hinted that we have given him this form purposely to enable him to draw. This, indeed, would be an argument of necessity, but this form has been judiciously imposed on him by man by regulation of the sexual intercourse, by a careful selection of specimens having some of the requisites to propagate from, until at last we have produced the massive weighty animal whose powers astonish us as well as benefit us.

6269. The *breast or coupler* (*f*) is the part between the point of the arms or shoulders, and which should be moderately wide and elastic, when it is otherwise, the horse is seldom durable, or strong, although he may be speedy. Neither have the lungs sufficient room for expansion, nor is it in such great extent of attachment frequently too it accompanies a general stiffness of ribs, and not of circular form in the carcass in general all which experience has shown to be necessary to the perfection of the machine. The breast may however be too wide it may also hang over or weigh beyond the perpendicular of the fore limbs, so as to overweigh the machine. This form, however, though unfavorable to the saddle horse, for the reasons just assigned is much desired in the heavy draught horse.

6270. The *back*. Where the withers and the back commences (*g*) the length should be moderate only for a long cylinder cannot be so strong as one of less length. Long backed horses are easy because the action and the reaction are considerable but what is gained in elasticity is lost in strength. When the back is too short, the extensors are so much approximated that they frequently overstretch each other and the hind feet strike the ground it, in progression the back should be nearly straight, it has natural an inclination as the line of its gravity. But this exists in very different degrees in different horses. Where the inclination towards is considerable such horses are called *saddle backed*, and are usually considered weak. But, to keep up the counterpoise, the crest in such horses is generally good. They also ride pleasantly, and commonly carry much apparent carcass sometimes indeed too much. When the back is curved upwards, it is called *roach backed* when considerably so, it is unfavourable to the liberty of action as well as to the celerity of motion. In these cases, to counteract the curve outward, the head is also usually carried low. A short-backed horse is in considerable request with many persons, who do not consider that when it is too much, so there is seldom great speed for the hinder extremities cannot be brought sufficiently under the body to propel the mass forward.

6271. The *loins* (*h*) may be considered as the part which extends from immediately behind the hinder edge of the saddle, when properly placed, to the rump. Anatomically it begins at the sacrum (*fig* 6267, *p*) whose process being sometimes defective or interrupted leave an indentation as though the union between the back and loins were incomplete and such horses are said to be badly loined but although it may in some measure deprive the muscles of some slight attachments, yet the evil is not so considerable as is imagined. The width of the loins is of considerable import to the strength of the animal, as it affords a greater surface for the attachment of the powerful muscles of the back and loins and the muscles themselves should be so prominent, so to seem to swallow the back loins amongst them. When the protuberances of the ilium or haunch bone are very prominent, the horse is said to be ragged hipped but it operates to his disadvantage only in appearance, as extent in these parts, being fit suitable to muscular attachment, is always beneficial.

6272. The *croup* extends from the loins to the setting on of the tail (*i*) It should be long and only slightly rounded, which is another characteristic of the blood or improved breed. In the cart horse, on the contrary it is so much shorter and much more considerably rounded (*fig* 6267, *p*). A low croup is in every point of view the most perfect, for it affords a very increased surface for muscular attachment, and although the large buttocks of the cart horse would at first sight convey an idea of great strength and extent, yet, attentively viewed, it will be found that the early rounding of the sacral line the low setting on of the tail, and the small space which necessarily exists between the hips and buttocks, all tend to lessen the surface of muscular attachment, compared with the broad croup wide haunches, and deep spread thighs of the blood horse.

6273. The *flank* (*k*), is the space contained between the ribs and haunches; when too extensive it indicates weakness, because it is the consequence of too long a back and such a horse is said not to be well ribbed up. When the transverse processes of the lumbar vertebrae are short, as in badly loined horses, this part is hollow. The flank is usually looked to also as indicative of the state of respiration, thus, when it rises and falls quicker than ordinary, unless violent exertion has just been used, it betokens present fever, or otherwise chronic disease of the lungs.

6274. The *belly* (*l*). Having taken a tour round the upper parts of the carcass, we will carry the survey downwards and forwards. Anteriorly the ribs should be wide upwards, and as much deepened below as possible, which affords what is termed great depth in the girth. This form greatly increases the surface of attachment of the motive organs, the muscles, and also allows room for the free expansion of the lungs, and consequently is favourable to the wind. Anteriorly the ribs should form the body as much as possible into a slender figure, that some of all others the most extended, and affording the best surface for the absorption of nutriment. These barrelled horses, as they are termed, are greatly esteemed, and desired to be leading in work and readily brought into condition, and more easily kept fit. When the chest is too flat and straight, the belly is also small. Hence, neither use the blood shews its vital principle from the fit, nor the hollow the deficiency issues from the intestines; these horses are therefore seldom durable. As less nutriment is taken up by the constitution, so less is excreted, thus also they are seldom good feeders;

1992. *The honey beekeeping*. We have already described the tangle, correctly to

called, which is supported by muscles as frequently to escape this consideration of it, by which the part immediately below it popularly receives the name of thigh, but which is, in fact, the leg.

6292. The leg (1 2), commonly called the thigh, in well formed horses is powerfully furnished with muscles, and very extended in its figure; it should also make a considerable angle with the femur or real thigh, and form a direct line under the hip or haunch; for the same reasons that make it desirable to have a long arm in the fore extremities, it is also advantageous that the leg should be so likewise and this is the form usual among all quadrupeds of speed.

6293. The hock (3) is the important joint immediately below the leg, or thigh commonly so called, and is interposed between the tibia and tarsal bones (Fig. 584), purposely to increase the extent of attachment and to break the shock of great exertion; it may be considered as the most complex and important joint of the body. Like the knee, it should be extended and broad; for, in proportion as the calcaneus or point of the hock (5) and which is the real heel, extends itself beyond the other bones, so the powerful tendo Achillis inserted into it, acts with a longer lever and with a greater increase of power. This joint is subject to several important diseases, which in the examination of a horse, require particular attention. When a soft purty swelling is discovered in the ply or bond of the hock (3), it is termed a *blood spavin*, which will be noticed among the diseases. It is, in fact, a similar enlargement with the windgalls before mentioned, and what has been said on them equally applies to these. When similar mucous capsules become enlarged on each side of the hock the enlargement receives the name of *thorough pin*. A small bursal enlargement is sometimes found at the very point of the hock (5) and is then called a *capsule*, to all which what has been said on windgalls applies, that they are only to be deemed of consequence when so large as to interfere with the motion of the parts they are situated with or near. Or as indicative of an undue portion of work. The ligaments at the back of the hock sometimes become strained or extended, and heat, inflammation and swelling follow which is then called a *curb*. As rest or very mild treatment soon reduces it, it is not to be considered as of great consequence. The inner part of the joint at the ply or bond, is some times attended with a skin affection similar to the malleaders before alluded to, and is called *scalders* (4); but the most serious disease to which the hock is liable is a disease of the ligaments of some of the tarsal bones. Sometimes one or more of these bones, or the ligaments which unite them, inflame and an exostosis or *spine* is formed to detect the existence of this affection the hocks should be attentively viewed from behind, when any enlargement in the spavin place (1, 4) may be easily detected. The mechanism of this joint will be further considered when we treat of the skeleton generally.

6294. The colour of horses does not depend on their real skin, as with man but upon an exterior beautiful covering which nature has given them called *hair* nevertheless, the hair is in some measure, influenced by the skin, as light-skinned horses have light hair and when the hair is light, the eyes are usually so likewise. Hair presents many varieties of tint, so horses are said to be of various colours. Buffon has conjectured that horses were originally of one colour, which he presumes to be bay but such wild horses as have been seen, and which have been supposed to be pure originals, have not justified this opinion. This same author has divided the colours of the horse into simple, compound and strange or extraordinary.

6295. The simple colours are bay, chestnut, dun, sorrel, white, and black. Bay is a very prevailing tint among European horses, and admits of many shades, but is admired in all. There are bright bays, blood bays, dark and deep bays. Brown bay is a very esteemed colour and consists of bay and black in unequal proportions in different horses. Brown horses are highly prized the darker varieties have usually beautiful tan markings, as about the muzzle &c. they have commonly also black manes and tails, with legs and feet of the same hue and it may be here remarked that horses of compounded colours, of whatsoever tint the mane and tail may be will be found invariably formed of one of the compounded colours. Thus light greys, which are a compound of black and white, have often white manes and tails. Sorrels, again, which are formed of white with a small proportion of red, have also frequently white manes and tails. Chestnut, which is also a very common colour admits of almost as many shades as the bay from the lightest tint to the deepest tone. Very light chestnuts have frequently still lighter manes and tails, with nearly legs and light feet, so marked they are certainly not to be chosen for strength, durability, or pliancy of temper. The buffalok punch, however, may be considered in some degree an exception although the true breed is hardly so light as those hinted at here. Dark chestnuts are considered, and with justice as fiery in their dispositions they are also more subject to contracted feet than horses of any other hue. Dun is a colour that has several varieties; it is sometimes accompanied with a white mane and tail at others they are seen even darker than the rest of the hair. In some, a list or line of deeper tint extends along the back which is regarded by some as an indication of hardihood. A similar line is sometimes seen in the bay. Dun horses do not appear to be at all influenced in their qualities by their colour, or rather no criteria are offered by it, for there are good, bad, and indifferent in all the varieties of shade. The sorrel is a variety of the chestnut, but not a favourite one. White as a native colour is not in much estimation, neither is it very common for many horses are white only through age, as all light-grey and flea-bitten horses become so. Black is a very usual colour, and in the large heavy northern breed it seems to be an original tint and perhaps it is to this their goodness may be attributed. For among the lighter breeds, there are more indifferent black horses than of any other colour. The temper of black horses are commonly in the extreme, either sluggish to stupidity or fiery to excess. The colour itself admits of many shades but a perfect black horse is more unusual than it is generally thought to be. A star on the forehead is common to relieve the ebony hue and in the absence of that, a few white hairs on the breast frequently interrupts the uniformity. It is, perhaps, on this principle that black horses have white legs so often as they do.

6296. The compounded colours may be considered as those in which the hairs are compounded, but not the colours themselves. Otherwise the bay, the chestnut, brown, &c. might be considered as compounded colours. The roan is a mixture of red and white its varieties are the common, the red and the dark. All the roans are esteemed. Grey admits of a great number of shades and varieties, but all are compounded of black and white, except the iron grey which receives a few bay hairs among the black and white; a considerable prejudice exists in favour of this colour. Greys are light or dark there are also the dappled, the markings of which are extremely beautiful and the silver grey. Grey horses become lighter by age many of white horses have been grey until age overtook them. Grey horses, like black, admit of no settled obstructs though unlike them, they are not to be generally disapproved of. They have, however all the extremes within their range; the darker ones are usually good the lighter ones are generally so.

6297. The extraordinary colours are not very numerous, and it may be remarked, that white is always the colour that, intermixed with distinct markings, in various proportions of bay, brown black or chestnut. Pie-bald is grey or white, with small bay spots. When these spots are very large, and have a marginal surface of lighter markings, they give the name *tiger coloured* and although they are uncommon with us they are not unfrequent in Germany and Barbary. Pie-bald is one of the most numerous extraordinary colours, and is usually composed of two colours, in distinct large markings.

Now and then a third interseces there are pie of all original colours with white, and all are held in estimation.

6298. *Colour, as a criterion of mental and personal qualities* is laid much stress on by many persons and long experience has shown that certain tints are usually accompanied by certain qualities of person or disposition. As a general rule, dark-coloured horses are certainly the best; but, as before observed, it is peculiar that black, as the darkest of all, should form an exception to this rule. Light shades appear unfavourable to strength and durability; they are also accompanied frequently with irritability and perverseness of temper. Something like a general law in the animal economy seems to prevail, to make white a distinctive mark of weakness. Age, which is the parent of weakness, brings with it white hairs, both in man and in horses, and most other quadrupeds. The hair formed after a wound has robbed a part of its original covering is often white, because the new formed surface is yet in a state of debility. It is likewise a fact well known among the observant, that the legs and feet when white are more obnoxious to disease than those of a darker tone. The Archa remarks, that light chestnut horses have not tender feet. It is the observance of these peculiarities that has at length guided our taste, and formed our judgment of beauty. With us much white on the legs is considered as a deformity, and is expressively called *four marked*, whereas pied markings in other parts are reckoned beautiful. In Africa, however, Captain Lyon informs us a superstitious dependence is placed on horses with legs and feet stockinged with white. It does not appear that climate has the same influence on the colour of horses as on that of other domesticated animals. In all latitudes in which the horse can live, he is black or white indiscriminately; but as he cannot endure extreme rigour, it is not necessary that he should vary

### SECT. III. *The Bony Anatomy or Osseous Structure of the Horse.*

6299. *All quadrupeds are formed on an earthy base called bone, and the assemblage of bony parts is called a skeleton.* Bones are formed of earth and membrane (1881) they are covered also by an investiture called periosteum. The earthy part is the last formed, and consolidates the bones as the animal becomes fitted to exert all his powers. This deposit of earth in the bones appears to be hastened by any thing that permanently quickens the circulation heat does this, and hence the human and brute inhabitants of warm climates come to perfection sooner than those of northern regions; but they are generally smaller for by preternaturally hastening the earthy deposit before the membranous part of the bones becomes fully evolved or grown, they do not attain the bulk they would be otherwise capable of. Undue exertion has the same effect and thus we learn why horses too early and too hard worked become stunted in their growth. Pressure likewise occasions an early and also a preternatural ossification in this way the parts of the spine which bear heavy loads present large masses of bone, brought on by this cause alone. For the same reasons, horses early worked put out splints, spavins, and other bony concretions. Bones are all of them more or less hollow within their cavities an oily fluid is secreted, called medulla or marrow which serves for their support, and that of the constitution generally. The bones have nerves, blood-vessels, and absorbents. Bones are capable of reproduction as proved by their uniting when broken, and also by the yearly renewal of the antlers of the deer which are not horn as in the ox or sheep, but pure bone. Bones are connected together by articulation when such articulation is moveable, it is termed a joint. In some cases bones articulate by suture or indentation of parts, as in the skull. We shall consider, in succession, the anatomy of the head, trunk, and extremities.

#### SUBJECT. 1 *Osseous Structure of the Head.*

6300. *The bones of the head are as follows.* The occipital (fig. 830, between a & b) which is the largest bone of the skull, in the colt is composed of several pieces which unite by age; it articulates with the atlas (a) or first of the cervical or neck vertebra. At its posterior surface it is perforated by a large hole which gives passage to the spinal marrow. The two frontal bones (b) unite also by age and behind them is lodged the anterior and inferior portion of the brain. A division of their bony surfaces forms two cavities called the frontal sinuses, which are lined by the nasal membrane throughout. The sagittal suture unites these two bones. The remainder of the bones of the skull are the two parietals the two temporals divided into a squamous and petrous portion, within the latter of which is situated the internal ear; and to the former the posterior or lower jaw articulates. The sphenoid and ethmoid bones are hollow and irregular serving to intersect and attach the others and also to assist by their cavities in extending the pituitary or smelling membrane.

6301. *The bones of the face are ten pairs and two single bones.* The nasal (c) pair within their union hold the alveolar arch or long cartilaginous plate which separates one nostril from the other. These bones also greatly assist to extend the surface of the smelling organ. In the old heavy breeds, it was very common to see these bones arch over outwards but in the improved breed, particularly in those approaching full blood, it is not uncommon to find them slightly curved inward. The same within these bones are the principal seat of glanders. The two maxillars form a considerable portion of the orbits of the eye. The two malar bones, or cheek bones occupy also a portion of the orbits. The superior maxillary bones (d) are the largest of the face bones, and contain all the upper molar teeth. The inferior or intermaxillary bones (e) are wanting in man, in whom the face is short these bones concur with the former in forming alveoli or sockets for lodging the teeth. The superior palatines, the inferior palatines the pterygoids, the two anterior and the two posterior sphenoidal bones, with the vomer or pharyngeal, make up the remaining facial bones, with the exception of the posterior maxillary or lower jaw bone (f) which on its anterior edge is pierced to lodge the teeth; at the upper part it extends itself into two angular branches, each of which ends in two processes and an intermaxillary groove. The superior of these processes articulates with the upper jaw. This bone throughout shows the most admirable mechanism; the molar or grinding teeth, on which mastic is dependant, and whose exertions are greatest, are placed near the centre of motion and as the upper jaw is most sensitive is fixed, or nearly so, it was necessary that the lower should have considerable extent of motion for the purpose of grinding; and it is accordingly so formed as to admit of motion in every direction. The os hyoides is a bone situated within the head at the root of the tongue, to which it serves as a support, and for the attachment of muscles.

6302. *The part of the bone are the hardest and most compact bones of the body.* There are usually forty of them in the horse, and there are thirty-six in the mare; in which latter the tushes are usually wanting. In uncastrated females they are divided into *superior maxillars*, and *inferior*, or according to the language of *fluxus and hemorrhoids*, into *twelve upper* (fig. 830, a, b, c) *four lower* (d, e), and

twenty four grinders which numbers are equally divided between the two jaws. The teeth are inserted into indentations or sockets between the bony plates of the jaw called alveoli, by cone-like roots. The bodies of the teeth are principally composed of two substances, one of the nature of common bone, giving bulk and form, and one of extreme hardness, called enamel, placed in man and carnivorous animals wholly

830

without the teeth to give strength and durability but in the horse and other Granivora, the latter particularly it is placed in the grinders, in perpendicular plates, within the body of the teeth; by which contrivance, a rough grinding surface is kept up, for the more bony parts wearing faster than the lamellae of enamel, it follows that ridges remain to triturate the vegetable matter that passes between the teeth.

633. *There are two sets of teeth* a temporary or milk set, and a permanent or adult set in which wise provision man and most brutes participate. The milk set are some of them as the molars, apparent at birth; there being usually six grinders in each jaw three on each side in the new born foal and which number of this set is never increased. The nippers begin to appear soon after birth and follow a regular order of succession until the animal is three or four months old at which time he begins to regale support from herbage as well as milk. The temporary set remove gradually one after another, had they all been displaced at the same time, or even had several of them fallen out together, the animal must have suffered great inconvenience, and perhaps have been starved. This removal which commences at the age of two years and a half and is completed between the fourth and fifth year, is effected by the action of the absorbents on their fangs, and appears to be occasioned by the stimulus of the pressure received from the growing teeth under them. For although these two sets appear with an interval of some years between them; yet the rudiments of both are formed at nearly the same period, and both sets may be thus seen in a dissected jaw. Regulated by the stimulus of necessity, as soon as the temporary set fall out, the permanent appears and that such appearance follows the necessity is evident; for a premature or accidental removal of the cut's teeth is soon followed by the appearance of the others. Dealers and breeders, aware of this draw the milk teeth to make their colts appear as horses. It was necessary there should be two sets of teeth; for as they grow slowly in proportion to the jaws, had there been but one only the disproportion of growth between the teeth and jaws must have separated them.

634. *The forms of the teeth* vary more than their structure. The incisives or nippers are round, which is favourable for the pressure they undergo the upper more so than the lower. On the upper surface a hollow is seen in the young teeth, which, not extending through the whole substance, naturally wears out with the wear of the tooth and as a considerable degree of regularity occurs in this wearing away in all horses, it has gradually settled into the general criterion of age. The nippers are not all of them exactly similar; the corner teeth differ most in being nearly triangular and in having an internal wall or side, which does not become level with the rest until long after those of the others. The canine teeth or tusks are permanent, appearing at about five years or rather earlier; these in the front jaw are usually nearer the nippers than those below. Each presents a slight curve, which follows the direction of all the canine or predatory teeth of other Mammalia. The pointed extremity wears away by age, leaving merely a buttoned process, which may serve as a guide to the age when a horse is supposed to be blundered, as it is called from a man of that name who was peculiarly dexterous in imitating on old teeth the distinctive cavity of youth. The molar or grinding teeth are stronger in the upper than in the lower jaw; which was necessary as they form the fixed point in the process of grinding. The upper surface presents nearly a long square, insulated from the alteration of the enamel with the bony portions and as the interior or upper teeth hang over the posterior so the ridges of the one set are received into the depressions of the other.

635. *Wear of the teeth.* The teeth, in a state of nature, would probably present a surface opposed to each other for mastication, to the latest period of the most protracted life but the removal of the animal from meat food to that which is hard and dry must occasion an unnatural wear in those organs; and hence, although the teeth of the horse even in a domesticated state, are not subject to the caries of the human; yet the grinders are liable to become thus injured by continued exertion. In the young or adult horse, the upper and under grinders do not meet each other horizontally on the contrary, they have naturally an inclination obliquely inwards and those of the upper jaw present small spaces between each other while those of the lower are more continuous; by which means, as the food, particularly its interrupted portions, as grain, becomes ground, it falls within the mouth to be replaced under the grinding sur-

ness, if necessary by the joint action of the tongue and muscles of the cheek. This arrangement becomes in a great measure frustrated in old horses, by the superior wear of the inner surface of the upper grinders, as well as by the general misapplication of the surfaces of both upper and under teeth, by constant attrition, when worn down nearly to the gums. The unfortunate animal feels sensible of this, and endeavours to remedy it by throwing the wear on the outer edge, by an inclination of the lower jaw and of the head in general, and which is so particular in its appearance as to engage the attention of the by-stander. This defect may be in a considerable degree remedied by casting the animal, and having opened and wedged the mouth to us to keep it so removing the inequalities with a well tempered coarse file, as much as may be. When the defect is considerable, and the horse is wild and quiet, it is better to file the inequalities every day which will gradually but effectually wear them down. It however happens, that the inclination thus to wear is commonly resumed and gradually the same loss of nutriment takes place in which case, soft moist food, as carrots, mashes, colic, or grating, must be substituted for harder substances, and if corn be actually necessary let it be bruised. Whenever an old horse betrays symptoms of want of condition or weakness, and especially, that neither his mode of feeding, nor his ratio of work will account for and particularly if whole grains should be found in his dung, his teeth should be examined carefully. This undue wearing of the teeth occasions another evil often, which is elevation of the cheeks, by reason of the projecting ragged surface of the uneven teeth, which can only be remedied by the removal of such portions. These projecting portions are called by farriers *rotten teeth*.

### SUMMARY. 2. Bony Anatomy of the Trunk

6306. The trunk of the skeleton consists of the spine, the pelvis, and the thorax or chest, composed of the ribs and sternum.

6307. The long column called the spine is made up of seven cervical, eighteen dorsal, six lumbar and five sacral vertebrae, with the addition of thirteen or fourteen small tail-bones. The spinal bones are thus divided on account of the varieties they present; they have however some characteristics in common. Each is composed of a spongy bony body with protruded points called processes, which processes unite, to form a hollow through which the spinal marrow is transmitted, and by some of these processes the vertebrae are articulated with each other as well as by their bodies, by which their strength as a column is much increased. Though but little motion exists between any two vertebrae yet the flexibility of the whole spine is considerable.

6308. The cervical or neck vertebrae (c) are called, by farriers and butchers the rack bones. It is remarkable, that, let the neck be long or short, the number of bones is the same in most quadrupeds. The first and second differ from the rest in figure, and present some other peculiarities. The first is the only one of those to which the great sensory ligament of the neck does not attach itself, which it would have interfered with freedom of motion. It articulates with the second by receiving its tubercular process within it, and from which process the second of these bones has been called *dens*. Between these two neck bones is situated a part, where the spinal marrow is exposed from any bony covering, at which part butchers plunge a pointed knife into what they call the pit of the neck, when they want to kill the animal instantaneously and without effusion of blood, whence it is called pithing. The remaining five neck bones are not very dissimilar from each other.

6309. The dorsal vertebrae (d) are now and then, though rarely nineteen in number they do not differ materially from each other but in the length of the spinous processes of the first seven or eight. It is to these elongated spines that we owe the height of the withers, and as the intention of these parts seems principally to serve as levers for the muscles of the back inserted into them, so we can readily understand why their increase or diminished height is favourable or unfavourable to progression. These like the former articulates with each other by processes, as well as by the anterior and posterior surfaces of their bodies; between each of which is interposed a substance, semi-cartilaginous in its structure which is most compressible at its sides, these permitting the motion of the spine.

6310. The lumbar vertebrae differ from the foregoing in having a longer body and very long transverse processes to make up for the deficiency of ribs in the loins. These bones often unite by the pressure of heavy weights, and sometimes spontaneously by age, and thus we need not be surprised at the stiffness with which some old horses rise when down.

6311. The five sacral vertebrae (s) are united into one to give strength to the column and to serve as a fixed support to the pelvis, or basin with which it is interwedged. From this detail it will appear how admirably this spinal column is adapted to its important functions of serving as a flexible but powerful support to the machine, and how by the formation of a large foramen within the substance of each vertebra, a bony canal is opened for the safeguard of the spinal marrow from which through lateral openings in these vertebrae, the spinal nerves are given off in pairs. The pelvis or basin (B) is composed of the sternum, the two os innominata and coccygia. The *os innominata* in the fetal colt before birth are each composed of the ilium, the ischium, and the pubis, all traces of which division are lost before birth. The *ilium* is the most considerable, and forms the haunches by a large unequal protuberance which, when very prominent, occasions the horse to be called ragged-hipped. The next largest portion is the *ischium* or *low bone*, on each side. It forms a part of the cavity or cup for the thigh bone and then stretches back also into a tuberosity which forms the point of the buttocks. The *pubis* or *share bone* is the least of the three in conjunction with the former it forms the acetabulum or cup-like cavity in which the head of the thigh-bone lodges. The pelvis or basin is attached to the sacrum by ligaments of immense strength but it has no bony union, by which means, as in the fore extremities, some play is given, and the jar of pure bony connection is avoided. The *os coccygia*, or bones of the tail, vary from eight to sixteen, but are very commonly thirteen or fourteen.

6312. The sternum or chest comprises the sternum or breast bone and the ribs. The sternum (s) of the horse is inclined like the keel of a ship to which the ribs are attached by strong ties. The ribs (r) are usually eighteen to each side, of which eight articulate with the sternum, and are called *true*, while the remaining ten, united together by intervening cartilages, are called *false ribs*. The centrals are the longest, these anterior as well as posterior are less so the first is placed perpendicularly the second lies on; and their obliquity, as well as dimensions, increase as they advance, so as to enlarge the chest in an almost circular form, which is the most desirable; but when they are less arched, the belly partakes of the defect, and a flat-sided horse is commonly a bad carvered one also.

### SUMMARY. 3. Bony Anatomy of the Extremities.

6313. An examination of the bony parts of the limbs excites our admiration at the wonderful mechanism displayed in their formation. Osseous portions also present themselves, which may be regarded as principally subservient in keeping up that vast chain of continuity and similarity observable throughout Nature's works. In the following explanation we shall have occasion to notice several of these.

6314. The scapula or shoulder blade (k, l), is a broad, flat, and rather triangular bone. It is very unlike the human scapula, having neither acromion, coracoid, nor recurrent process, neither is its situation at all similar to the human blade bone applied to the back for in this instance the horse may be said to

have no proper back, but to be made up of sides and chest. In man the scapula is in a direct angle with the humerus, but in the horse it does not pass out of the plane of the arm. Its superior surface is furnished with a considerable cartilage (c) by means of which its surface is supported without weight. The posterior surface ends in a superficial cavity called glenoid, which receives the head of the humerus or arm bone. It is divided in its upper surface by its spine. The shoulder blade, as has been already shown in the exterior conformation, has neither bony nor ligamentous union but is held in its situation by very powerful muscles, as the serratus major, pectoralis, and others. Its usual situation is to a plane perpendicular to the horizon at an angle of thirty degrees and it has a motion in its greatest extent of twenty degrees hence, as it does not pass beyond the perpendicular backwards, so the more oblique its natural situation, the more extensive are its motions.

6315 The *Acromion* or *arm bone* (m) is so concealed by muscles as to be overlooked by a cursory observer and hence the radius or neck bone is popularly called the arm. It extends from what is called the point of the shoulder but which in fact, is a protuberance of its own to the elbow forming an angle with the scapula, and extending obliquely backwards as that does forwards. Near its upper extremity it sends off a very powerful head to articulate with the shoulder blade. The motions of the humerus are necessarily confined to a removal from its inclined point backward to the perpendicular line of the body. When this bone is too long it carries the fore legs too much under the animal, and if this defect is joined to a shallow upright shoulder the evil will be increased. It, however, fortunately happens that both the angle and extent of these two parts are usually regulated by each other.

6316 The *fore arm* (n o) is composed of the *radius* (o o), and an appendage united to it, which, in man and some animals, forms the *ulna* (n n) but which, as the leg of the horse requires no rotary motion, was unnecessary in him. Here however to keep the link of resemblance in all her children as the higher order Nature has stretched out a large process which in the cat is really distinct, and may then deserve the name of *ulna*, and in the adult horse unites with the radius, and serves as an attachment to muscles. On the slightest inspection of the skeleton it will appear how much the motions of the fore leg must depend on the length and obliquity of this process, which acting on the principle of a lever in the extension of the arm must necessarily, as it is either long or short, make all the difference between a long and a short purchase. The brachial of the arm, as it is called, at this part, will, from this reasoning, be seen to be very important. This bone articulates with the knee by its anterior portion.

6317 The *carpus* or *wrist* called the *knee* (p p) is composed of seven bones, whose principal uses appear to be to extend the surface of attachment of ligaments and tendons, and by their interruptions to lessen the shocks of progression. It may be remarked that all hoofed quadrupeds have the anterior extremities permanently in the state of pronation, or with what is called the back of the foot turned outwards. The carpal bones articulate with each other, and have one unobscured capular ligament by which means the smallest wound of the knee which penetrates this ligament has the effect of opening the whole joint, hence the quantity of synovia or joint oil which escapes in these cases, and hence also the dangerous consequences which ensue.

6318 The *metacarpus* (q q, r r) *canon*, or *shank* is formed of one large metacarpal bone (q) and two small ones (r). Here the wide palm of the human and the paw of the digitated animal is formed into one solid cylindrical bone and two small additaments called *spurs* bones which are united with it by strong ligamentary attachment, converted by age into a bony one. Although these additions may somewhat increase the surface of attachment, their principal use appears to be to keep up the connection with the digit, of which they appear the rudiments. In the cow there are no spurs bones, but the uniformity is more perfectly kept up by the division of the hoof therefore the canon branches at its inferior surface into clefts for the reception of the two claws.

6319 The *pastern* (t t) The rest of the extremity below the canon, consists of one phalange only comprising all the mechanism, and a double portion of complexity of all the phalanges of the digitated tribes. Four bones enter into its composition with two small *sesamoids* (s s) to each fetlock placed there not only to act as a spring and prevent concussion but to throw the tension of the foot which runs over them farther from the centre of motion. The pastern bone is situated obliquely flexing and on this obliquity depends the ease and elasticity of the motion of the animal nevertheless when it is too long, it requires great efforts in the tendons and ligaments to preserve it in its situation and thus long jointed horses must be more subject to fatigue and to strains than others.

6320 The *lower pastern* or *coronary bone* (t v) receives the great pastern and below expands into a considerable surface articulating with the coffin and its sesular bones.

6321 The *coffin bone* (v v) forms the *third phalange*, and corresponds in shape with the hoof. It is very porous, and laterally receives two prominent cartilages. It is around the outer surface of this bone that the sensible laminae are attached, and the inferior surface receives the flexor tendon.

6322 The *navicular bone* or *shuttle bone* is situated at the posterior part of the coffin, and unites with that and the preceding bone.

6323. The *posterior extremities differ much from the anterior* not only in their superior strength and in the different lengths and directions of the parts, but also, in some degree in their uses.

6324 The *femur* or *thigh bone* (3, 4) is the largest of the body its vast indentations and ranges almost peculiar to it, show the great strength of the muscles inserted into it. It articulates with the acetabulum or hip joint by a strong head called the *subspinous*. In this situation it is held not only by a powerful capular ligament, but by still more powerful muscles, but by an admirable contrivance resulting from a ligamentous rope, which springs immediately from the middle of its head, and is firmly fixed within the socket of the joint. In its natural situation it is not perpendicular as the human femur but inclines to an angle of about forty five degrees. This bone presents large protuberances for the attachment of very powerful muscles called trochanters. Throughout it exhibits a mechanism saving the combined qualities of celerity and strength unknown to other animals. The inferior end of this bone is received by its condyles into depressions of the tibia, while the patella, or knee-pan, slides over the anterior portions of both bones.

6325. The *patella* (5) which is by farmers called the *stifle*, is nearly angular and serves for the insertion of some of the strongest muscles of the thigh which are then continued down to the leg. It thus appears to act as a pulley.

6326. The *fibula* or *leg bone* (6, 6) is usually in horsemen's language, called the *thigh*. It is a bone formed of a large epiphysis, with a small attached part called the *fibula* (7) a long body and an irregular inferior end, adapted to the peculiarities in shape of the principal bones of the back, with which it articulates. The obliquity in the situation of this bone corresponds with that of the femur being as oblique backwards as the femur is forwards. The length of the tibia is a prominent character in all animals of quick progression in this respect it corresponds with the fore arm and the remarks made on that apply with even more force, to this—that length is advantageous to the celerity but less so to the ease, of the motion.

6327 The *fibula* (7 7) forms a prominent instance in common with the splint bones of what was remarked in the outset of our ontological detail of the extremities—that many parts, whose uses were not apparent would be found to be organs of harmony placed in the body to prevent interruption to the completing the general plan of animal organisation. In this way the *fibula* appears but a process springing from the posterior part of the tibia, forming but the rudiments of the human bone of that name.

In the ox it is wanting; in the dog and cat, as requiring numerous motions in their limbs, it is, on the contrary, perfect.

6322. *The femur, or bone of the horse* (16, 30), is a striking instance of the perfect mechanism displayed in the bony structure of this admirable animal. It is formed by an assemblage of six bones, and sometimes of seven; while in the ox, sheep, and deer, there are seldom more than five. Between these bones there is little motion, yet there is sufficient to give a spring to the parts, and to preserve the joints from the effects of shock, &c. As the hump standing is generally received as the standard of comparison, we must, in order to a proper consideration of the hock, consider it as the instep and heel; and all the parts beyond it as the feet. The human tibia, and that of some beasts, as the monkey and some varieties of the bear makes a right angle with the tibia in standing or walking; but, in the horse, the hock makes an open angle with the tibia, and is far removed from the ground. In him and the greater number of quadrupeds, all the bones, from the hock downwards, are much elongated, and form a part of the upright pillar of the limb. In the horse, therefore, the point of the hock is the true point of the heel, and as in the human figure, the great twisted tendons of the gastrocnemius muscles are inserted into it but the application of these Achilles would be too forced here. A broad hock, as already observed in the exterior conformation, may be now still more plainly seen to be very important to strength and speed, for the longer the calcaneum or heel bone of the hock, the longer must be the lever that the muscles of the thigh act by; and a very slight increase or diminution in its length must make a very great difference in the power of the joint. It is by this tendon acting on this mechanism, that, when the animal has inclined the angle between the canon and the tibia, or in other words, when the extremities are bent under him in the gallop or trot, he is enabled to open it again. The bones of the hock, like those of the knee, are united together by strong ligamentous fibres; and it is to an inflammation of these uniting the calcaneum and osseous bones, that the disease called *curb* is to be attributed. And to a similar inflammatory affection of the ligaments in the front of the hocks, that swelling of the *front* stage are owing. In the latter disease the peritæum and bones themselves become affected. The remainder of the bones below do not differ so essentially from the corresponding bones in the fore extremities as to need an individual description. It may however be remarked, that the hinder canon or shank bone is longer than the fore, and that the pastern is also the same, but is less oblique in its situation by which wise provision the horse is enabled to elevate and sustain his body entirely on his hinder parts without danger which would not have been the case if the obliquity of these parts had been considerable.

#### SUMMARY. 4. General Functions of the Bony Skeleton.

6323. *The skeleton of the horse* must be considered as a mechanism of admirable wisdom and contrivance, which having considered in detail, we offer the following summary of its functions generally as a whole. It will be found to present nearly a quadrilateral figure, having an inclined cylinder resting on four supporting pillars. The spinal column as the inclined cylinder serves as a base for the soft parts, and is found not truly horizontal, but dipping downwards over the fore legs by which the propelling force of the hinder extremities is relieved by the maximum of strength thus transferred. The increased weight of the hinder part of the cylinder is admirably counterpoised by the head and neck, which are projected forwards; by these means leaving the line of direction near the centre of the whole. The length of a cylinder may be such as not to support its own weight; Nature, therefore, has limited the length of the spines of animals hence, *crivine pariter* a long-backed horse must be weaker than a short one; and thus, likewise, small horses can carry proportionably more than larger ones. The four pillars which support this cylinder are not perpendicular partially but they are so totally for a perpendicular drawn from their common centre of gravity will be found to fall nearly in their common base, by which means they are supported as firmly as though their individual axes had been in a line perpendicular to the horizon. Had they been perpendicularly opposed to each other there could have been but little elasticity, and consequent ease in motion every exertion would have proved a jar and every increased effort would have produced laceration or fracture. To increase our admiration of this mechanism, we need only turn our attention to the contra-disposition of these angles in the fore and hinder supporting pillars. Had these angles presented themselves in the same direction, the body must have been precipitated forward or backward but each offering a counteraction to the other the body is firmly sustained within them.

6324. *The legs* must be operated on by muscles, for this deviation from a perpendicular direction in the various bony portions of the limbs must necessarily have powers to correct it, which is effected by the muscles and wherever the angles are found most extensive, the muscles will be found proportionally strong and large. This muscular exertion, to counterbalance the angular inclination, occasions fatigue; as the set of muscles immediately employed becoming weary the animal is obliged to call another set into action, which change is necessarily more or less frequent as the animal is weaker or stronger.

6325. *The extent of the action of the bony portions of the extremities* is the product of the length and direction of the various parts entering their composition, and of the different angles they are capable of forming, as progression itself is effected by these angles closing, and suddenly extending themselves again. The force of the action arises from the direction of the component parts of the angles, in combination with the agency of the muscles. The repetition of the action is dependent on the muscles alone but as the original action moves out of the length and direction of the parts, so it will be evident that in every subsequent repetition, it will be more or less extensive, as these are more or less perfect in their formation, even though the muscular exertions should be the same thus, some strong animals cannot move so fast as others with less strength, as the cart-horse and racer or greyhound and mastiff.

6326. *The bony mechanism of the fore and hinder extremities presents some differences.* That of the fore limb may be said to exhibit altogether a different character. The fore-leg bones are much less angular and appear crossed purposely to receive the weight imposed on them by the impulse of the hinder limbs. This weight they are destined to sustain, until the elevation is forced on them by the tendency the general inclined mass has to meet the ground, or to find its common centre in the earth. The fore extremities, under this view of the matter, could not have been placed with equal wisdom in any other situation, nor have taken any other form. The hinder extremities having less weight on them, and at no time bearing an increase of pressure, as the fore do by the impetus communicated from behind, are much more angular; and their angles, by being thrown into a back-ward direction afford the necessary impetus for the propulsion of the body forward. This important operation of impelling the mass being almost wholly dependent on the hind extremities, as that of sustaining it is principally confined to the fore extremities so the former are also much stronger in point of muscular apparatus; by which their angles can be advantageously opened and closed with superior effect in progression.

#### SECT. IV Anatomy and Physiology of the soft Parts.

6327. *We shall include under appendages to bone,* the muscles and tendons, blood-vessels, absorbents, nerves and glands, integuments, head, ear, eye, nose, mouth, neck, chest, abdomen, organs of generation, and the foot.

##### SUMMARY. 1 Appendages to Bone, the Muscles, and Tendons

6328. *The appendages to bone* are cartilages or gristle, peritæum, medulla or marrow ligaments, and synovia or joint oil.

6335 *Cartilages* are of three kinds, *articular* (1887) which cover the ends of the bones by a thin layer uniting them to each other; *semi-articular* or such as are placed between bones immovably joined, *unattached*, as those of the ears and larynx, and *temporary*, as the ends of bones in very young animals before their cartilage is completed. The general nature of cartilage is smooth white, solid, elastic, and hard.

6336 *The pericardium* is a general uniting membrane to bones and their appendages (1882). on the skull it is called *pericranium* when it covers ligaments, *peridontium* and *periosteodermis*, when it invests cartilage. Its uses appear to be to furnish vessels to the bone. It is little sensible, except under inflammation, when it becomes highly so.

6337 *Marrow* or *marrow* is a soft fatty substance deposited in the cavities of bones.

6338 *Ligaments* (1881) are close compact, fibrous substances, of immense strength in the horse, necessary to bones as a connecting medium. Ligaments are also a common membrane in every part of the body. Ligament is considered indelible: there are however many exceptions of which the cervical and metacarpal and metatarsal are instances. In some cases they are semicartilaginous. The *capsular* ligaments attach and suspend parts, as that of the thigh bone to its socket, &c. *Capsular* ligaments surround the two opposed ends of jointed bones, and form a complete cavity.

6339 *The synovia* or joint oil, being secreted from the inner surface of the capsular ligaments, fills up this cavity and affords a slippery medium, which enables the bones to slide readily over each other.

6340 *Muscle* is that part of the body of the horse which we term flesh to distinguish it from skin, gristle, bone, ligament, &c. Muscles appear composed of bundles of reddish fibres, the ultimate division of which it is impossible to trace and as the motions of an animal are very various and as almost all motion is operated through the agency of the muscles so the peculiar shape they take on is very varied. To the generality of muscles, particularly to those ending in bones, is added a portion of a very different nature, called *tendon*.

6341 *Tendons* are inextensible, tough fibrous substances, of a whitish colour, expanded into thin layers, they are called *aponeuroses*. The tendons are eminently useful to muscles, diminishing their size without decreasing their strength. What would have become of the light elegant limb, had the large muscular masses been continued to their terminations below in equal dimensions? Muscles are highly vascular as their colour testifies but the tendons are very little so hence their powers of life are very different one can regenerate itself with ease, the other with extreme difficulty. The muscles also possess a large share of nerve, and consequently of sensibility and irritability to which properties the surprising phenomena they exhibit must be attributed while their extreme vascularity furnishes them with powers to keep the energies requisite for these agencies. They contract and shorten at pleasure, acquire a power of acting dependent on their situation and can change the fixed for the movable point, *viz* *verru*.

6342 *Muscles are voluntary and involuntary*. The former are immediately under the influence of the will, as those of the legs, eyes, mouth &c. Involuntary muscles are such as are not under the guidance of the will, and whose functions go on without control, as the heart, the respiratory and digestive muscular organs. Muscles are many of them covered by a cellular or membranous covering, called *fascia* and their tendons by another but stronger investiture called *sheath or sheath*. At the tendinous extremity there is usually a capsule containing a quantity of lubricating mucus, the diseased increase of which forms what is termed *windgall*.

## SUBJECT 2. Blood-vessels of the Horse

6343 *The arteries are long membranous canals* composed of three strata, which are called *tunica* or coats as, an external elastic, a middle muscular and an internal cuticular. Each of these coats is the cause of some important phenomena, as well in disease as in health. The *elastic* power enables them to admit a larger quantity of blood at one time than another and thus they are turgid under inflammation by this also they can adapt themselves to a smaller quantity than usual otherwise small hæmorrhages would prove fatal. The muscular tunica appears to exist in much greater proportion in the horse than in man and this accounts for his greater tendency to inflammation and also why inflammatory affections run to their terminations so much sooner in the horse than in man. The arteries gradually decrease in their diameter as they proceed from the heart. Our knowledge of the terminations of these vessels is very confined we know they terminate by anastomosis, or by one branch uniting with another. They terminate in veins, and they terminate on secreting surfaces, in which case their contents become changed and the secretion appears under a totally different form. Another common termination of the arteries is by exhalant openings, by which sweat is produced. The use of the arteries is evidently to convey blood from the heart to different parts of the body and according to the part the artery proceeds from, or proceeds to, so does it receive an appropriate name.

6344 *The aorta* is the principal member of this system. Originating from the left ventricle of the heart it soon divides into two branches one of which the *anterior* or *aorta ascendens* (fig. 833 p.) proceeds forward to be divided into two principal divisions the *carotids* (q) by which the head is furnished and the *axillaries*, by which the fore limbs receive their blood, under the names of humeral radial, and metacarpal arteries and the *posterior* or *aorta descendens* (o) which is distributed to the trunk and hinder extremities.

6345 *The pulmonary artery* is a trunk of five or six inches in length arising out of the anterior ventricle of the heart, and continued by the side of the aorta. It soon divides and enters the lungs, through which it ramifies.

6346 *The veins* are also membranous canals which begin where the arteries end and return that blood which has been distributed by the arteries. They have less solidity and possess two tunics or coats only. They usually accompany the arteries in their course, but are more numerous, being wisely divided into superficial and a deep-seated set, to avoid the dangerous effects of interruption. To prevent the return of the blood they are furnished with *valves* also.

6347 *The original venal trunks of the horse* are ten in number. The anterior clava, the posterior clava, and eight pulmonary to which may be added the *vena porta*.

6348 *The vena cava* passes out of the heart by two trunks from separate parts of the right auricle. The *anterior* or *vina ascendens* (fig. 833 n.) opposite to the first rib, divides into four principal trunks two *axillaries*, and two *jugulars*, (fig. 833 p.) The *axillaries* furnish the fore limbs under the names of the humeral ulnar and the metacarpals. The *jugulars* (r) run up one on each side of the trachea to return the blood of the head. The *posterior* or *vina descendens* (o) returns the blood from the body and hinder extremities.

6349 *The vena porta* is formed from the veins returning the blood from the viscera which uniting to enter a set of *striated* veins, are ramified through all parts of the liver where the blood having undergone some remarkable alterations is returned by the *vina hepatica*, and enters the heart by the posterior clava.

6350 *The blood is a homogeneous fluid*, contained in the heart, arteries, and veins, and constantly circulating through the whole body. It appears formed with the body is red in the arteries, and purple, brown, or glister in the veins. The coagulable is composed of red globules, whose intensity of colour is less in the horse than in man. A red colour is not necessary to the essential properties of blood, seeing the blood of some animals is white and even some parts of the horse's body are furnished with colourless blood as the transparent part of the eye &c. The coagulable lymph or fibrin (1841) appears the most essential part of the blood, and that from which all the parts are formed. The serum seems to dilute the whole. The quantity contained in the body is uncertain, young animals possess more than older and hence bear bodily injuries better. It is less in quantity in fat than in lean animals, and is

demonstrated than in those which run wild. An animal will lose one fifth of its blood before it dies. A horse has half-an-hour's pulse without apparent injury. Probably the quantity contained in the body may vary according to circumstances between one eighth and one tenth of the whole mass is a fair medium.

6301. *The pulse.* From the contraction of the heart and consequent dilatation of the arteries to receive the blood, and pass it onward to all parts of the body which is called the *systole*—so a dilatation of the heart and contraction of the arteries necessarily occurs, which is called the *astole*—and these two causes operating alternately produce the phenomenon of circulation. The momentary increase in capacity in the diameter of the artery is called the *pulse*. As there is seldom disease present without some alteration in the circulation also, so the pulse is attended to as an indication of health or disease. The circulation being carried on over the whole body, the pulse may be felt universally—but some situations are more favourable than others—as the heart itself the *aorta*, at the root of the ear &c. but the most convenient of all is at the branch of the posterior jaw where the maxillary artery may be readily detected (*fig. 630, g*). The natural pulse in the horse is about 45 beats in a minute, in the ox the same, in man 70, in the dog 90. When the pulse is much accelerated, the circulation is accelerated also. If, with its quickness, fulness of vessels and hardness are apparent, the circulation is *morbidly* hurried, and inflammation general or partial is present.

#### SUMMARY 3. *Absorbents of the Horse*

6302. *The absorbent system* is a very extraordinary and a very important one—for if the blood builds up and repairs parts, the absorbents pull down, remove, and take them away again. They are composed of the *lymphatics* and *lacteals*. Both kinds, although thin and transparent, are strong and appear to have a contractile power—where very minute they are called *capillaries*. The lacteal absorbents are situated in the mesentery and intestines, whence they draw the chyle, or nutritious fluid by which the blood is nourished and augmented. The chyle is carried forward from the mesentery into a tube called the *thoracic duct*, which, passing up by the side of the *aorta*, pours its contents into the heart through the medium of the jugular vein. The *lymphatic absorbents* differ from the latter only in being situated over the whole body, and having the reverse of the vessels of the body—whereas the lacteals appear to absorb the chyle only. From numerous facts, we know that the various organs are continually suffering a destruction and a removal of parts, and that what the absorbents take away the arteries renew—and to the constant change, most of the alterations of the body are to be attributed with regard to the structure of parts. We use our power over these vessels in the horse medicinally. We stimulate the absorbents to take up dissolved solutions of fluids from various parts of the body, as in watery swellings in the legs by mercury and by friction, or by pressure in the way of bandage. When deposits are made of hard matter or hæmorrhoids, we stimulate them by blistering or by firing. It is by stimulating the absorbents that splints and spavins are removed. Exercise is a very powerful stimulus to absorbents—thus it is that swelled legs are removed by half an hour's exercise. In the horse, the lymphatics are more liable to disease than the lacteals, but in man the reverse. Farcy diseases the lymphatics irreparably.

#### SUMMARY 4. *Nerves and Glands of the Horse*

6303. *The nervous system of the horse* is composed of white medullary cords, springing from the brain and spinal marrow—whence they are generally distinguished into the cerebral and spinal nerves—the internal structure of these bodies is fibrous, and their ramifications extend to every part of the body—it is supposed that the brain is the seat of sensation and volition—and that the nerves are only the messengers of it. The sensibility of a part is usually proportioned to the number and size of its nerves. Nervous influence occasions motion. From some cause, unknown to us, some motions are voluntary and some involuntary—but both are brought about by nervous agency. As the nerves are the media of sensation so a division of their cords has lately been attempted, with success, to relieve certain painful affections the most prominent instance is, in the division of the posterior nerves for the relief of the painful affection of flounder. Tetanus, or locked jaw which seems a morbid irritation on the nerves, has been recommended to be treated in the same way.

6304. *The cerebral nerves* arising in pairs immediately from the brain, are the olfactory optic, trochlear, oculi, trigemini, abducent, auditory lingual, par vagum, and the pair called the intercostal or great sympathics, from its extensive connection.

6305. *The spinal nerves* are those which arise immediately from the spinal marrow—as the cervical, thoracic, lumbar, sacral, and coccygeal, and posterior nerves—the dorsal the lumbar, cervical, sciatic, popliteal, sacral, and the nerves to the posterior extremities which correspond with those of the anterior.

6306. *The glands* are numerous, and placed in every part of the body—they may be characterised as secretory bodies, composed of all the different vessels enclosed in a membrane—their office appears to be to secrete or form some fluid, as the liver secretes bile and the kidney urine. They are classed into follicular, glandular, glandular, and conglomerate—they also receive specific names according to their situation, or according to the fluid they secrete, as lachrymal, salivary &c.

#### SUMMARY 5. *Integuments of the Horse's Body.*

6307. *The common integuments* may be considered as the hair the cuticle, the epidermis, or incrustable or outer skin, the rete mucosum, which is immediately under this, the cuticle, movable or true skin, the cellular membranes, which contain fat and other fluids, and the panniculus carnosus or fleshy pannicle to which may be added, the hoofs, nails or hoofs, which we shall describe separately.

6308. *Hair* is the clothing of brutes, and hence is very important to them, and so it enters largely into the arts, it is also important to us. (1851.) It appears to be a production of the true skin, arising from a tubercle and, which penetrates the rete and cuticle in the form of an elongated cone. In some parts hairs appear singly, as about the muzzle, in others in masses, as on the mane, tail, and over the body generally as an inclined congested mass—hair varies in colour and therefore appears by nature intended both for ornament and use.

6309. *The cuticle is situated immediately under the hair* (1842) and appears a hard membrane covering purposely placed to guard or defend the sensible skin underneath. The cuticle lines many of the large openings of the body, as the mouth, whence it is continued into the stomach, lining one half of it. It is perforated by innumerable small vessels that give out and take in various matters—through these blisters act on the true skin, induce it, and force it to secrete a quantity of fluid, which thus pushes the cuticle from the skin. It exists before birth, and is speedily renewed after birth when accidentally destroyed and, like the true skin, thickens by pressure—it is constantly undergoing changes, it exfoliates in the form of powder or little scales, over every part of the body and is that substance called dandruff which groomers are so careful to remove with the currycomb.

6310. *The rete mucosum* is a mucilaginous substance placed like a net between layers of cuticle and cuticle, and although very universal in animal nature, its use is unknown.

6311. *The skin, or true skin.* (1867.) The very general investiture of the body is situated immediately under the rete mucosum, it is very vascular and is furnished with innumerable small villous processes of sensitive sensibility, and which, without doubt, were intended to constitute it as the real organ of touch. It is much thickened by pressure, seen from the beatings they are subjected to, have it of immense thickness on the rump. It naturally also exists in various degrees of density according to the wants of the animal. Like the cuticle it is perforated by numerous openings which correspond with those of the latter membrane. Its composition appears principally gelatinous, and hence it is employed in the manufacture of glue, its gelatine uniting with the matter called tannin, becomes insoluble

in water and then forms leather and the value of the horse's hide in this particular is sufficiently known.

5352. *Adipose membrane and fat.* These form very considerable parts of the body of most animals. The adipose membrane is not so universal as the skin, some parts are completely without it as the eyelids, ears, sheath, and some portions of the extremities. It is cellular but the cells fortunately do not communicate or the fat would gravitate. The fat is the unctuous juice poured or rather secreted into these cells. It appears in greater quantities in some parts than in others, and in different degrees of consistence; in the body of some it is hard and stout in others within the bones it is oleaginous in all. Different quadrupeds have their fat of different degrees of consistence, from the firm suet of the ox, and the tallow of the sheep, to the soft lard of the hog, and the intermediate state of the horse. It guards the parts, it preserves warmth but above all, it is a depôt against occasional want thus a fat animal can sustain itself without food much longer than a lean one. The torpid bear comes from his hibernation emaciated, because his constitution has been depending on his fat.

5353. *Cuticular membrane.* (1849.) This complete investiture of the body enters every part, and is formed of communicating cells as we see by the practice of butchers who blow up their meat and also by the emphysematous effects of a fractured rib, and the gaseous distention in some putrid diseases. It exists in different quantities and under various modifications of density throughout the body and is a very universal medium of connection in the form of ligament.

5354. *Frenaceous carnosus* (1848.) The fleshy penicillus was kindly given to quadrupeds in lieu of hands, to enable them to corrugate or pecker the skin, and thus to shake off dust and insects. It is a thus muscular expansion peculiar to brutes, but not to all the swine family being denied it. By its attachments it can operate variously as we see by the uses the horse makes of it. It is very vascular and sensible, also, from the numerous nerves which enter it.

#### SUMMARY 6 The Head generally.

5355. *The parts of the head* are external and internal some of these have been touched on, as the mandibles, &c. such as have not will follow in the order of their magnitude or situation.

5356. *The brain of the horse* (fig. 531 a, b, c) contained within the hollow of the skull, is so similar to

531

that of man that to describe the one is to portray the other. Like the human it is composed of cerebrum (a), cerebellum (b) and med. its prolongs (c). The medulla spinalis is a direct continuation of the brain in the form of a medullary cord, called the path or spinal marrow (d) which passes out of the skull through the occipital foramen. The brain appears to be the organ of consciousness, and the nerves which arise out of the medullary cord are the messengers by which sensation and volition are distributed to the various parts of the body.

#### SUMMARY 7 The Ear.

5357. *The ears of the horse* are composed of inner and outer parts. The internal parts do not differ from those of the human, but the outer are adapted to his situation and habits. These exterior parts are composed of the skin, the outer hair the cartilages and the muscles by which they are moved. The skin within the ears is furnished with sebaceous glands, which secrete a buttery matter noxious to insects and further to guard against these, it is filled with hair which the false taste of grooms induces them to remove, and thus to expose the animal to dust, hail, rain, and insects.

6305. The form of the ear is dependent on the concha cartilage, which is found pointed and small in the Arabian, but large and broad in the heavy breeds. The cavity within the concha is thrown into folds throughout, which increases its surface, and reflects the concave waves. This outer ear is attached to the internal, by connecting cartilaginous portions and appropriate ligaments. The parts of the internal ear are, the cochlea, auditorius internus, or passage; the membrana tympani, or separating membrane between the external and internal parts; the tympanum, drum, or barrel of the ear; and the labyrinth. The Eustachian tube is an opening at the upper and anterior edge of the hollow of the tympanum, forming a duct which is in part bony and in part cartilaginous, extending from the tympanum to a large and peculiar cavity at the posterior part of the nasal fossa.

6306. The sense of hearing is formed through the medium of the expansion of the soft portion of the auditory nerve over the internal ear sounds, therefore, entering the cavity of the concha, are reflected alternately from its sides into the tympanum, whose oscillations are imparted to the brain.

#### SUMMARY 8. The Eye and its Appendages.

6370. The appendages to the eye are, first, a funnel-shaped cavity formed by the concurrence of the bones of the skull called the orbit not placed directly in front as in man, but inclining laterally to enable the animal to embrace a larger field of view. The eyelids are an upper and under, of which the upper is the most considerable and enjoys the greatest motion. United they form an admirable curtain to defend the eye from dust, insects, and the light during sleep; and are moved by two appropriate muscles. Attached to the edge of each is a cartilaginous rim, called the tarsus. The cilia, or eyelashes, are not, as in man, above and below the upper lid only is furnished with hairs, and these are not placed in one row, but in several smaller rows. The horse has no supercilia or eyebrows, unless we reckon as such the few long hairs over the orbits. The lachrymal gland is a body lodged within the upper part of the orbit; it is furnished with five or six excretory ducts, which secrete the lachrymæ or tears to lubricate the surface of the globe. The superfluous tears are carried off by two openings at the inner angle, called *lacrimal foramina*, by which means the tears are at once carried into the nose, and not as in man first into a lachrymal sac. The *corneolus lachrymalis* is a small black substance in view at the inner canthus, whose office appears to be to direct the tears aright in this course. The *lens*, or *refracting membrane*, is an important part, seen when the eye is drawn inward, but which is at all other times hidden within the fleshy matter surrounding the globe of the eye. Though called a membrane it is cartilaginous, and when the eye is forcibly withdrawn into the socket, it is pressed out from the inner angle and passes completely over the surface of the globe, to which its shape is adapted. A moderate pressure only shows about half of it and it is thus seen in tetanus or stag eel, by the action of the retractor muscle, and under inflammation of the eye it also becomes visible, which has led ignorant farmers to cut it off under a suspicion that it formed one cause of the disease. The use of this refracting membrane cannot be for a moment dubious. It is denied to man and to monkeys, because they, having hands, can with their fingers remove dust and dirt from the eyes but to the horse and most other quadrupeds it is essentially necessary for these purposes.

832

6371. A diagram of the eye (fig. 832.) displays the transparent cornea in front of its globe (a) the crystalline lens (b) its posterior convexity (c) its anterior convexity (d) the iris or curtain (e, f), the anterior chamber occupied by the aqueous humour of the pupil (g) the posterior chamber filled with the vitreous humour (h) the retina (i) the choroid coat (k), the sclerotic coat (l) and optic nerve (m) rays of light showing the different degrees of refraction they suffer in passing through the humours of the eye (n, o).

6372. The globe of the eye is composed of coats, chambers, and humours, and is operated on in its movements by muscles. It may be considered as forming a large cup posteriorly with a smaller cup applied to its margin anteriorly or as though the segment of a large sphere were adapted to that of a smaller one. The substance which gives figure and consistence to the larger segment is the sclerotic coat (l) which is very firm and dense. The anterior cup or segment is supplied by the cornea which is transparent, and formed of thin concentric plates of very different degrees of convexity in different animals, and often in similar animals to a defect in which is ascribed the indistinct vision or starting of some horses. The cornea (a) is vascular and sensible, and in an inflamed state it admits the red blood, as we see by the universal redness over the whole at other times it admits only the colourless parts of that fluid. Immediately within the sclerotic coat is a thin vascular membrane called the choroid (k) which is spread over it nearly as far as the cornea, where it turns in and expands into the ciliary processes. It also by a peculiar fold forms a ligament, after which is produced another projection into the cavity of the eye, termed the aorta. It is here continuous, and presents a veil perforated in the centre.

6373. The pupil of the eye (g) is the perforation which is seen annular in the human, oblong in the horse, ox and sheep, and perpendicular in the cat. The anterior surface of the aorta is covered with a membrane, termed iris, on which the colour of the eye depends in man it is grey brown black or blue in the horse it is usually brown but now and then white, when the animal is said to be wall-eyed. At the central margin of the iris are seen, in a strong light, some little globular bodies or bags, covered with a black pigment. They are usually attached to the upper margin only, but when any exist on the lower they are small; they have been mistaken for disease. The iris (e, f) is capable of accommodating itself to circumstances that is, it can enlarge the diameter of the central aperture or pupil (g) so as to admit or shut out the rays of light. Over the central surface of the choroid expansion is spread a dark mucous substance, called *nigra pigmentum*. In animals, whose vision is distinct at night, this pigment is found of a lighter colour in man it is very dark, and his crepuscular vision is, therefore, in distinct. In the grazing tribes it is of a greenish cast, lost in asure blue in the predaceous tribes it is still lighter. Under this pigment is the mucous expansion peculiar to quadrupeds, called *tapetum*. The optic nerve (m) penetrates the sclerotic coat, and becomes expanded on its inner surface, in a membranous lamina of exquisite texture, called *retina*. On this, it is supposed, objects are painted, and thus taken cognizance of by the brain.

6374. The humours of the eye are the vitreous, the crystalline, and the aqueous. The vitreous humour (h) is of a jelly-like consistence, and occupies all the globe, except those parts taken up by the other humours. The crystalline humour forms a lens-like body of moderate consistence, and is, therefore, more properly called a lens (b). It is doubly convex (c, d) its posterior side resting in a concavity of the vitreous humour. It is not of equal consistence throughout, being much firmer in the middle. Different animals have the lens of different figures, to suit the purposes of their existence. In fishes it is nearly spherical but in quadrupeds, lens-like. It is a denser opacity of this body that forms cataract. The aqueous humour is a limpid fluid which fills up the spaces not occupied by those already described.

6375. The muscles of the eye. The motions of the eyeballs are operated by seven muscles; four rest or straight, which elevate, depress, and draw to and from two oblique which rotate the eye and a retractor

or choanoid, peculiar to quadrupeds, to draw the eye within the socket and thus preserve it from danger which draws the globe inward.

637d. *The phenomena of vision.* If the diagram be examined it will be evident that the eye of the horse presents an optical mechanism of exquisite workmanship and mechanism, admirably fitted to collect the luminous rays from the various objects around, and to transmit them with truth to the brain. If the luminous rays reflected from objects passed through the eye in a rectilinear course, as they do through the atmosphere, no cognizance at all useful to the animal could be taken of them by the eye. All would be glare and indistinctness, but being refracted or bent by the media through which they pass, the rays finally meet at a point called their focus or focal point. Neither would one simple line of refraction have been sufficient to answer all the purposes of perfect vision under its various modifications. It is necessary that the refraction should be increased in its passage by increased degrees of density in the media of its transit (n. n.). In the passage of the rays through the cornea and aqueous humour they meet, encounter their first refraction, and it is evident, that the more convex the anterior portion of the eye may be the more will this refraction be increased. We need not, therefore, be surprised that a poggler or horse with this form of eye, should start. The next and largest degree of bending which the rays receive occurs in their passage through the crystalline lens which from its lenticular form must necessarily be considerable. In their progress through the vitreous humour a farther refraction is effected, till meeting in a point on the retina, a perfect representation of the object or objects viewed is obtained; the rays forming in their passage numerous cones, the base of which will be the object viewed, and the apex of each a radiant point. Amidst the number of objects around it appears that the eye has a capability of effecting rays from such only as are immediately necessary for the purposes of the animal it belongs to hence, although the general field of view may fall under an angle of vision, yet such rays only as are immediately capable of this convergency produce effect, all others are lost in the black pigment of the eye, apparently placed there purposely to absorb the superfluous rays. As the eye must necessarily have a vast variety of objects painted on it, those distances are widely different, there must be some optical adjustment of the powers of the part to enable it to effect a distinct vision of all objects near or remote, but whether this takes place by means of the angle formed on the two opposite axes, or as has been more lately taught, by a muscular power in the lens itself, is not yet satisfactorily ascertained. Certain it is that after the loss of one eye, time is required both in the human and brute subject for the remaining eye to learn to adjust itself to judge of relative distances; which fact is certainly in favour of the opinion that an angle formed between the eyes regulates the judgment of distances. In this way we can account for the well known fact, that hunters, which have before the loss of an eye been excellent and sure keepers, have afterwards lost the power of measuring their leaps. Were it not for some adjustment of the optical organ itself, the rays reflected from objects very near the eye would fall behind it, and those from distant ones would from being almost parallel, meet together before the retina. The mechanical adjustment of the focus is also assisted in some measure by the iris which contracts almost to a point when we look at a very minute object, and by this means only permits such rays to pass through as penetrate the centre of the lens, by which such rays will be very much refracted, but when the eye regards distant objects, the iris becomes dilated, and the rays are then viewed through the edges of the lens, and their inclination is thereby lessened.

637f. *The criteria of soundness in the eyes* are gained by a careful examination of them; and which experience has shown to be best made by placing the horse within a stable, with his head nearly approaching the stable door, which should be fully open. Small eyes are found more prone to inflammation than large and large poggling eyes are more liable to accompany a starting horse than lesser ones and when the convexity is extreme, not only is the starting in proportion, but such eyes are more liable than others to become affected with the disease popularly called glass eyes, but medically grata serena. It is not, however to be understood that all starters have defective eyes; many are so from natural thinness and still more from harsh usage. The eyes should be examined together not only to observe whether each presents an equal degree of clearness in the transparent part and within the pupil, but also that an equal degree of contraction exists between each of the pupils. This is of much consequence if any inequality in size or form be observable between the pupils, the least of them has been in some way affected, and will probably become so again. It is even more suspicious when a torrid milkeness appears on any part of the transparent portion, and equally so, when the inferior part looks other than clear or in a very strong light, with a lively bluish tinge. When it is at all turbid, viewed under various aspects, regard it attentively, and there may probably be found an inward speck of perfect white which is the nucleus or central point of an incipient cataract.

637h. *A glassy greenish cast in the eye should excite suspicion*, and the hand should be placed over such eye so as to exclude the light remove the head suddenly and watch the motions of the iris or curtain of the pupil. If it do not contract, carry the examination still further and it will probably be found such eyes are totally blind. A blind horse usually carries his ears about, as though in alarm, on his leaving the stable he also lifts his feet on such occasions, particularly in strange quarters, higher than a sound horse.

#### SUBJECT 9. The Nose and Sense of Smelling

637a. *The organs of smell* is, in most quadrupeds, the next in importance to that of vision, and in many points of view it is even of more consequence. With the herbivorous tribe, it forms their principal means of judging between the noxious and the innoxious. It is not therefore to be wondered at, that it should in these tribes form so large a portion of the head, nor that it should be so exquisitely gifted with sensibility or so admirably fitted to answer its important purpose. The external parts of the nasal organ are the two nostrils, and so much of their convolutions and linings as come into immediate view. Internally these two cavities are carried upwards into the pharynx, but completely divided by a cartilaginous septum (see 631. f). In this course they communicate with numerous openings and cavities, formed within the bones of the skull (8800) the whole of which are lined by one continuous membrane of exquisite vascularity and sensibility; being largely furnished with blood-vessels, which gives them such a ready tendency to inflame and become red as we witness under only a slight degree of exertion and give us more evidently when violent colds or inflammations on the chest are present. Its sensibility is derived from the olfactory nerves, which are spread over all its surface. It is this membrane which is the peculiar seat of glanders becoming first inflamed, and next ulcerated throughout its extent and as the membrane itself appears to be continued to the pharynx and larynx so we need not wonder why the glanders proceeds to disease the lungs; nor why a common cold, which is at first a simple inflammation of the membrane so readily degenerates into inflammation of the lungs. The common integuments or coverings of these parts are extended over the nose, but it is little furnished with fat. Of hairs it has a fine thin covering to the edges of the nostrils, and a longer set, which are carefully removed in trimming. By a fold of the skin, within which is a cartilage, the false nostril, as it is termed, is formed, whose use appears to be to keep open the canal for the transmission of air and yet to offer an interruption to extraneous matter. When the nostrils are a little separated, a small canal may be seen which is the nasal duct for the transmission of the superfluous moisture from the eyes. The horse breathes or respirs wholly through his nostrils in all ordinary cases.

6380. *The sense of smelling.* The volatile particles from all odorous bodies are continually passing off from them, and consequently some must reach the olfactory organs, whose capability of taking cognizance of their qualities appears derived as before pointed out, by the expansion of nervous fibres from the olfactory nerves which transmit impressions to the brain.

SECTION 10. *The Cavity of the Mouth.*

680. *The external parts of the mouth* are the lips, cheeks, and beard. *The lips* are made up of fleshy masses so disposed as to give them motion every way they are covered over with a very fine expansion of skin almost devoid of hair their exquisite sensibility forms them into an organ of touch; and in this point of view they may be considered as supplying the part of the points of the fingers in man. *The cheeks* are equally muscular and movable, but are more furnished with hair and the beard, in addition to this thin hairy expansion, has a set of long hairs.

681. *The internal parts of the mouth* are the teeth already described (669) the gums, the alveolar edges, the palate, the tongue, and the parts of the great posterior cavity. The gums are a spongy substance which embraces and holds fast the teeth in their alveolar sockets. The membrane which covers the gums at the lower part of the channel forms a kind of fold to connect and confine the tongue on each side. These folds are called the *bars* and are apt to be mistaken and cut off as excrescences. The bars are the spaces in the jaw left between the grinders and nipper teeth and which man ever ready to take advantage of for his own purposes, has made use of to ensure obedience by placing on its sensitive surface the pressure of the bridle-bit. The palate forms a bony arch, covered by membranous folds, which are apt, when the stomach is affected to become swollen, in which case the horse is said to have the lampas or lamper. (6446.) By means of these rugose folds the food is retained within the mouth. The *curtains of the palate* or *velum palatæ*, which is situated at the extreme end of the palatine arch is stretched directly across the hinder mouth and is not intercepted as in man by the pendulous body termed uvula. This palate curtain is intended to shut out the communication between the mouth and the great cavity of the fauces, which it does at all times, except when the horse is swallowing at which period the curtain is forced back and the food passes. From this cause likewise the horse is prevented from breathing but by his nostrils and when any air does pass by the mouth, as in coughing, crib-biting &c. it is only effected by a forcible displacement of the curtain.

682. *The tongue* is a long fleshy mass (fig. 831. e) which adapts itself below to the form of the channel, and above to the arch of the palate its external surface is rough by means of papillæ, which are inclined backwards, and thus resist the loss of the food received within the mouth. In some animals, as the ox, bear &c. they are very large, and in the cat pointed. The tongue is a very principal organ in mastication, carrying, by its great mobility the food into every direction until fully acted upon and finally passing it into the pharynx.

683. *Sense of feeling.* It is not observed that this sense is so diversified in brutes as in man but it is instinctively so correct, that it seldom errs in the herbivorous tribes and when it does, there is reason to suspect some present defect in the organ, arising from morbid sympathy which (as in the instance of salt-water of which at some times horses will drink immoderately) prompts them to take in matters they are accustomed to refuse. Taste was given to brutes to regulate their other senses, and thus there are few plants or substances whose application to the tongue under ordinary circumstances, produces an agreeable effect but such as are proper for food. Nature, therefore, stimulates her creatures to search for edibles by a double motive the calls of hunger and the pleasures of taste and these are usually in union, for the nausea of repletion destroys the appetite of taste.

684. *The pharynx.* The cavities of the mouth and nose terminate in the great cavity of the fauces called by this name, to which also is appended another lesser opening called the larynx, immediately appropriate to the entrance of the tracheæ or windpipe. Within this great chamber, at the afterpart of the mouth, shut from it by a membrane only is the Eustachian cavity into which the Eustachian tube opens, and which great membranous hollow is unknown in man and most quadrupeds (fig. 831. d.) Its use is not understood, but it is probably connected with the voice.

685. *The larynx* is situated at the posterior part of the former cavity and appears as a cartilaginous box between the os hyoides, to which it is attached for support. This cartilaginous box or entrance to the windpipe, is formed of several pieces, and is furnished with a kind of movable door which, in ordinary cases, exactly fills up the cavity left by the arch of the palate curtain thereby shutting the cavity of the mouth, and forcing the animal to breathe through his nasal openings. In extraordinary cases, as when the animal swallows food, this cartilage is forced down and then it becomes a door to the glottis or funnel part of the tracheæ, and thus prevents the entrance of extraneous matter into the lungs. All these parts are operated on by numerous muscles.

686. *The voice.* The larynx has also another important office in being the organ of the voice. The cartilages of the larynx are very movable on one another, and are furnished with muscular cords, which tighten or relax them; besides which, they are also furnished with peculiar and appropriate sacs or cavities, independent of the tracheal opening, and which are of different magnitudes and directions in different animals. The cartilages of the larynx being acted on by the cordæ vocales, produce different degrees of density and consequently different degrees of expansion in the laryngeal sacs by which, either in expiration or inspiration, are produced different degrees of vibration, and consequent intonation. Nothing appears produced wholly by expiration through the nose, as are most of the tones of the horse's voice. This is proved by tilting the nasal cartilage, which wholly stops it. *Knacker*ing as it is termed, is only a lower neigh, with shorter deeper and less forcible tones. The former sound is used as a call, the latter as either call or recognition. It is likewise, when used mildly, significant of joy and affection, and is then beautifully answered. The horse has an acute sound produced by inspiration, usually descriptive of lust in most other cases his intonations are accompanied by expirations nor does it appear that the tongue or teeth of the horse are much concerned in the modulations of his voice.

687. *The parotid glands* or in the language of farmers, the *stees* are two considerable bodies on each side of the head, extended from the base of the ear around the angle of the jaw. Each parotid is a conglomerate gland, furnished with numerous little ducts, which unite into one, and enter the mouth about the second molar tooth. These glands furnish saliva for the use of the mouth and it is an induration and gathering, either in them or the maxillary glands, which form the strangles of young horses. Assistant to these in the furnishing of saliva are the *mandibular glands*, situated within the branches of the lower jaw and the *sublingual* also.

SECTION 11. *The Neck.*

688. *The external parts of the neck* are the common coverings which have been described, the cervical ligament, the muscles, and the jugular or neck veins &c. The *cervical ligament* (fig. 831. z) is a very strong substance, in some parts semimuscular and in all extremely elastic, stretched from the occipital bone along the back of all the cervical vertebrae except the first. Continued on the spinous processes of the dorsal vertebrae, it fills up the dip or depression of the spinal column of the neck, so completely as to form the neck either into a plane, or an elegantly convex line upwards. By its extreme tenacity the ponderous mass of the head is preserved in its situation, without the necessity of an immense mass of muscle which would, without this contrivance, have been necessary. It is to an injury received at the upper and anterior part of this ligament, that the pole evil is owing. The muscles of the neck are too numerous to allow of particularization; it is sufficient to say they most of them run longitudinally the jugular veins run one on each side of the neck superficially on the side of the tracheæ and windpipe, and form the vessel usually tied from (fig. 833. r). A few inches before they reach the angle of the jaw each divides to furnish the head.

689. *The external parts of the neck* are the vertebrae, within which passes the spinal marrow. The *carotid arteries* pass up under the jugular veins, near the oesophagus (fig. 833. s) The *tracheæ* or wind-

pipe (fig 833 *g*) is a large canal for the transmission of air formed by alternate rings of membrane and segments of cartilage, rendering it at once flexible and cylindrically hollow. The *tracheæ ægæ* (fig 831 *h* & 833 *e*) is the continuation of the funnel like cavity of the pharynx. It is externally muscular, and internally membranous and cuticular by which formation it is elastic, to allow of distention in the act of swallowing. The œsophagus penetrates the chest within the mediastinum, and passing along the spine (fig 833 *f*) through an opening in the diaphragm, terminates in the stomach.

### SUBJECT 12. The Thorax or Chest.

6301. The chest of the horse is bounded anteriorly by the matters filling up the space between the two first ribs, posteriorly by the diaphragm, laterally by the ribs above by the vertebrae, and below by the sternum or breast bone. In dissecting the horse after the intercostal membranes, muscles &c are thrown back (fig 831 *bbb*) there appear the lobes of the lungs (*ccc*) the heart (*d*) mediastinum or membranous division of the chest (*e*), the sternum or breast-bone (*f*) the costiform cartilage (*g*) and tendinous centre of the diaphragm (*h* &).

6302. When the chest is opened a smooth polished membrane is seen which covers the surface, and then is reflected over its contents this is called the pleura. And by a junction of the two pleura a division of the chest into two nearly equal portions is effected, which membranous division is called the mediastinum. By this division of the chest into two parts, very important benefits arise, as when one cavity is opened the lungs immediately collapse but the respiration may be carried on by the other. In a similar manner ulcerations may proceed to destroy the lobes of one side of the chest, as in glanders, but may be checked by the mediastinum from proceeding to the other. The pleura does not, as in man, appear to take on inflammation independently of the substance of the lungs; thus the horse is not subject to pleurisy. The thymus gland, which is a considerable body in the colt, and which forms the sweetbread in calves is hardly discernible in the old horse. It is situated between the folds of the mediastinum, but its uses are unknown.

6303. The diaphragm or *metathra* (fig 831 *i*, *k* is a very important part of the body of the horse, dividing the chest from the belly by a physical, extended and narrow muscle. Further upwards than forwards. Its fibres radiate from their origin to unite to one tendinous centre *A*. In a state of rest it is anteriorly convex and posteriorly concave but at each inspiration these appearances are nearly reversed. 6306. It is perforated for the passage of the vena cava, the aorta, the *œsophagus*, thoracic duct, and œsophagus all which pass through it by means of three openings. It has been found ruptured in some desperate cases of broken wind.

6304. The heart (fig 811 *c*) is the great agent of circulation, and is made independent of the will, were it otherwise man and other animals might cease to live at their own discretion. The pericardium is first seen surrounding the heart so completely that it swims within it by means of a little fluid termed liquor pericardii. The heart is a composition of membranous and muscular fibres, having four principal cavities, and several openings. It is situated within the mediastinum so as to occupy a cavity of its own distinct from either side of the chest. Its base is in a line with the dorsal vertebrae and its apex is directed to the left of the sternum between the eighth and ninth ribs. Its two ventricles are immediately within its body and its two auricles are rather without, appended to it. The left ventricle contains arterial blood and from it originates all the arteries except the pulmonary. The right ventricle is the reservoir of the venous blood, and it receives all the veins except the pulmonary. Within the ventricles are valves to prevent the return of the blood. The auricles are less muscular than the ventricles, the left, or pulmonary opens into the left ventricle and the right communicates with the right ventricle into the right and larger auricle the anterior and posterior cava enter by two openings, and into the left, the pulmonary veins pass.

6305. The circulation of the blood may be shortly described as originating with the left ventricle of the heart which sends its blood, by means of the great vessel called the aorta, to all parts of the body. The blood thus distributed is collected again by the veins from all parts, and is then returned into the heart by means of the two cava, which put their contents into the right auricle which immediately forces it into the right ventricle. From the right ventricle it is again forced out into the pulmonary artery which carries it throughout the lungs to undergo a change, and to be finally returned by eight trunks into the left auricle which immediately empties it into the left ventricle to renew the process described.

6306. The lungs are spongy masses divided into right and left, with less divisions called lobes. Their colour varies according to age thus, in the colt they are of a light lively pink in the full grown horse they approach to a greyer tinge and in the very old subject they are of a still deeper tone. The bronchia are continuations of the trachea or windpipe which, dividing on its entrance into the chest, ramifies throughout the substance of the lungs, giving these masses their spongy cellular structure, in which distribution the air vessels are accompanied by ramifications of the pulmonary artery and veins. From the extreme vascularity of these parts they are very liable to inflammation.

6307. The theory of respiration. By some extraordinary sympathy the colt at birth gasps, and air rushes into the lungs before collapsed having once felt this stimulus, by a common consent between the diaphragm and intercostal muscles, the cavity of the chest is diminished to expel the air reserved, and to inspire a fresh quantity and which process is then continued through life. The body appears vitally nourished by two sources the one through the medium of digestion the other by means of the blood itself which in its progress through the body gives out its vital principles of heat to the mass and vitality to the muscular fibre, for unless the blood effect its part in the contractile phenomena it will be in vain for nervous influence to exert its power. Having given out these principles, it is returned by the veins, and is passed forwards into the lungs, circulating throughout their substance, and imbuing, by their contiguous or continuity with the air vessels, oxygen gas from the atmospheric air contained in them. In return for the oxygen received, carbon is given out which passes off in the form of aqueous vapour. As the blood is renovated, so the air it acted on is deteriorated, and is therefore expired from the chest to make room for a fresh inhalation, to oxygenate a fresh quantity of blood, and thus to renovate afresh the vital powers subservient to its influence.

### SUBJECT 13. The Abdomen

6308. The viscera of the abdomen include the stomach (fig 833 *a*) lobes of the liver (*bb*), cœcums or cauli attached to the whole inferior curvature of the stomach (*c*) the spleen (*d*) the kidneys (*e*) the rectum (*f*) the ovary (*g*), the uterus (*h*), the bladder distended with urine (*i*) the diaphragm or muscular partition dividing the belly from the chest (*k*), œsophagus or gullet proceeding to the stomach (*l*) lacteal (*m*) vena cava ascendens (*n*); aorta descendens (*o*) which passes through the abdomen (*p*), as does the vena cava descendens (*q*) the aorta anteaorta (*r*), carotid arteries (*s*) jugular veins (*t*) œsophagus (*u*) and maxillary artery forming the most convenient situation for feeling the pulse (*v*) which completes the viscera and general appearance of the horse when laid open.

6309. The abdomen or cavity of the belly is the largest cavity of the body and forms an extensive oral vena, containing very much of the blood which may be considered as the chyliferous, the urinary and the spermatic, all which are invested by a membrane called the peritonæum, which, after covering each of these organs separately is reflected over the cavity of the belly itself. It is very strong, and very elastic, as we perceive by the effects of dropsy, great distension, and likewise by the morasses in pregnancy. The *omentum* or *caud* (*o*) is the fatty apron which first prevents itself on opening an animal's

body, extending in some, as the dog, pig, &c. into the pelvis but in the horse it is less considerable, from which he is not subjected to epistaxis as they are. In uses are unknown.

640. The stomach and its digestive functions. The horse has one stomach only, and that a very small one, drawing a very wide line of separation by this means between his family and the ruminants. In fact

893

as recipient orifice, a strong band of circular fibres is very evident, which effectually constricts this part, and prevents regurgitation or vomiting in the horse, except under extraordinary circumstances of muscular relaxation and sympathy. It has been already shown that the anterior part of the alimentary canal, as the mouth, throat, and gullet, are lined with cuticle or skin. This cuticle is continued into the stomach, and lines nearly a half of its internal surface, whose office seems to be a more perfect comminution of the food, which the horse has no opportunity of ruminate like the ox, sheep, &c. The villous or serrated portion of the stomach is thrown into folds, so as greatly to increase its surface here the comminuted food in its passage becomes saturated with the solvent gastric juice, and is then passed forward into the intestines.

6401. The derangements of the stomach may be explained from its anatomy. Though small, and its sensible parts still smaller yet it is subject to more disease, and to more frequent derangement, than is generally supposed. It has been proved to be muscular and that its digestive functions are performed by means of its muscularity. It has also been shown that the contractile energy of the muscular fibres is mainly gained from the oxygen derived from the blood; whatever tends to interrupt this separation, as an unhealthy state of the lungs, too quick action of them, &c. must derange the action of the stomach also. The perfection of its digestive powers is also derived from its secreting healthy gastric juice, consequently whatever interrupts this process must likewise interfere with stomachic health, and that such health is more often impaired than is generally supposed, and that many ailments, attributed to other causes, are really dependent on an affection of this organ. Experience and observation will fully evince. One of our most frequent complaint among horsemen, that horses are out of condition, and unfit for work, the appearance are various, but are all well known yet it is seldom considered that it is owing, in every seven cases out of ten, to the stomach being morbidly affected. (6425.) It is evident that too full feeding must derange it, not only by keeping it constantly distended, and thus weakening its capacity but by retarding too much on its secreting office, and requiring an enormous quantity of gastric fluid to saturate an undue quantity of farinaceous matter. The folds, that are frequently found on its cuticular coat, and are there probably herules, sometimes displace themselves, and settle on the villous part, where they must occasion ulcers and probable inflammation.

6402. The intestines (fig. 531 A, B) in the horse may be considered not merely as absorbing organs alone, as in man and many animals, but as really digestive organs, and continuations of the stomachic viscera. This is more particularly the case with the small intestine, and may therefore entitle them to the term of alimentary canal, and the large to that of the excremental. The former measure from twenty one to twenty three yards in length and the latter from seven and a half to eight yards and a half, according to the size of the animal. The duodenum is the first of the small intestine, commencing at the pyloric orifice of the stomach; the jejunum, which is the next and larger portion, and the ileum (fig. 531 C), which is still longer, form the remainder. The alimentary canal in its structure does not differ from the sensible part of the stomach, having like that two planes of muscular fibres, a circular and a longitudinal, by which its peristaltic motions are regulated; the longitudinal shortening the canal, and the circular distending its use. The alimentary part of the intestinal canal ends with this small gut, which itself

the stomach of the horse may be regarded as intermediate between the tritinating muscular one of birds, and the membranous one of the Giraffes. It is peculiarly constructed to keep up this intermediate character, being partly membranous, partly muscular, and partly cuticular, in which latter formation much of its peculiarity consists, and which it shares in common with man, rat, and mouse whose habits of living on grain give them a like claim to this wise provision. In a state of rest, or only moderately distended, its direction is across the abdomen, with its two orifices directed upwards but the cardiac or recipient orifice to which the oesophagus is attached, the most so while the pyloric or expelling orifice is rather lower and more inclined backward. The situation of the stomach is immediately contiguous to the diaphragm or great breathing muscle (fig. 533 A & B) from which we are at no loss to understand why a very full meal obstructs respiration and why it is so imprudent to gallop a horse very hard after drinking or eating fully. Small as the stomach is in a natural state, it is yet capable of great distension, as has been witnessed in stomach staggers, when upwards of half a hundred weight of undigested food has been extracted from it. The membranous portion of the stomach is gained from the peritoneum within this is situated its muscular part, principally composed of longitudinal and transverse layers, by which its motions in digestion are regulated. Around the cardiac

terminates abruptly in the caecum or first of the large intestines (fig. 834 a), and which intestine commences what has been termed the excrementitious canal. This excretion is effected in such a manner as to leave, by a protrusion of its surface inwards, a kind of valvular apparatus, which prevents the return of the contents.

834. The large intestine (fig. 831 & b) in the horse are really deserving of that name, being very capacious; while in man and carnivorous animals they are little different from the small. They occupy and completely fill up the lower portion of the abdomen: the caecum occupies the right side, and carries its blind end towards the diaphragm, which is not furnished with an appendix as in man. A careful inspection of this intestine will show that the appendicular or excrementitious canal does not wholly apply to it, but that, on the contrary, it performs some of the offices attributed to the smaller intestines. The colon commences small from the side of the base of the caecum but soon enlarging it makes a turn round the abdomen, when contracting it ends in the rectum, and passes backwards to the anus. Along the course of the large intestines are muscular bands, which throw their surfaces into folds, and also form them into a continuation of cells (fig. 831. m). By these means, the matters are detained to be acted on more fully and finally they are expelled in dry hardened balls.

835. The digestive process in the horse is one of the most curious as well as one of the most important which goes on in the body. The various actions of an animal body produce relaxation and waste, which are indicated by fatigue and hunger. To restore the one, rest is required, and to restore the other food becomes necessary. For the herbivorous tribes, vegetable matter is sought for which being collected, is masticated by the grinders and mixed with saliva, until it becomes a softened mass, when it is passed backwards by the tongue and molar muscles through the arch of the palate in the form of a bolus. Received into the pharynx, which rises to receive it, and the action of which forces down the epiglottis all impediment is removed to its falling in the open funnel of the oesophagus; which having received it the spiral fibres of the oesophagus force it inwards into the stomach. While the food remains within the cuticular part, it is acted on by pressure but being further removed, it meets the action of the gastric fluid, by which it is reduced to a pulaceous mass called chyme. In this state it is passed into the small intestines for in the horse, as before observed, the process of digestion is by no means completed in the stomach as in man and many animals. The exertions of the horse require that he should eat largely and nutritiously but the bulky & sordid of the ox would have ill suited with his necessities for he is not only strong, but his motions are designed to be quick also. It was therefore necessary that some speciality should occur to meet these opposing disorders. This consists in the mode of digestion which being but partially completed in the stomach requires a less bulk in that organ, the intestines participating in the labour. A horse will eat two or three pecks of corn or ten pounds of hay at a meal and yet in a natural state his stomach will not hold half of either. He will also drink two pails of water when the same organ cannot hold one. What is taken into the stomach is therefore quickly passed through it, and more is required. A horse cannot fast long without injury and pain; his food does not produce a lasting effect in the constitution as animal food does in the Carnivora. A dog fed once a day will thrive and when fed every other day only will not suffer materially but no horse fed once a day would support himself even oxen and sheep, as having a slower digestion and more intestinal room, can bear fasting better than the horse. As an animal destined for quick as well as great exertions, he wants prompt him to take in a moderate portion of food only at a time, which his digestive powers peculiarly fit him to convert into nutriment quickly and efficiently by distributing the task through a long tract of canal instead of confining it, as in man and the Carnivora to one simple organ, the stomach.

836. The chyme passes into the duodenum from the stomach where it receives the addition of the pancreatic and biliary fluids, whose ducts open into that part of the intestinal tracts. Conducted onwards by the creeping peristaltic motion, it passes through this long alimentary tract rather rapidly in the horse; but it remains sufficiently long to receive further additions from the secreting surfaces of the smaller intestines, and probably to have its work of division and absorption begun in it. Arrived at the larger part of the intestinal tract, it is purposely delayed to be fully strained and separated, the open mouths of the lacteals spread over the villous surface receiving the nutritious part under the name of chyle, and the residue being carried backward, and thrown out as dung. The chylous cristles belong to minute tubes termed lacteals which pass onwards enveloped in membranous folds termed mesentery until uniting in one trunk called thoracic duct their contents are poured into the heart, whereby they become mixed with and converted into blood, producing an increase in its quantity as the lactation it receives in the lungs is an amelioration of its quality which it has been shown is equally necessary to the animal.

837. The liver may also be considered as a digestive organ (fig. 833. f & g) inasmuch as it secretes a fluid whose office appears to be to quicken the action of the intestines at the same time that perhaps the very matter separated tends to purify that blood which has been already distributed to the chyliferous viscera. All other animals, except the horse and deer, are furnished with a receptacle for the bile, where it may be retained and rendered more acrid but the horse has no gall bladder and, in his foetal state, another speciality presents itself in this organ which is, that he is deprived of a canalus venter, and thus the whole of the abdominal blood flows through the liver. From this simplicity of structure in the horse he is seldom affected with obstructed or concrete bile; but the organ itself is liable to inflammation and also to a chronic disease of it through the medium of the stomach.

838. The pancreas is an assistant to digestion also, as we have reason to conclude by its pouring its contents into the duodenum with the bile. It is situated behind the liver between the stomach and left kidney.

839. The spleen, or mill (fig. 833. d) is a spongy body situated at the greater extremity of the stomach its use is likewise not clearly ascertained; but it has been supposed to be that of a reservoir of blood for the stomach.

840. The kidneys are two secretory glands (a & c) situated in the lumbar region the right more forward than the left. The structure of the kidneys exhibits an external reddish part, an internal whitish part, and a cavity called the pelvis. From this cavity passes out the duct called the ureter, and brings with it the urine which is secreted within the kidney. The ureters convey the urine to the bladder.

841. The ureter appears to be a fecal separation from the blood, and is in some measure connected with the skin in its office. Thus, when the perspiration is great, the urine is less and on the contrary in winter when the perspiration is small, the urine is more considerable. The kidneys of the horse are more easily stimulated into increased action by diuretics than those of man or of most other animals and substances which would not appear potent act with violence on his urinary organs. Thus raw-burnt hay kiln-dried oats, &c. will produce diabetes.

842. The bladder of the horse (fig. 833. e) is a membranous sac for the reception of the urine. It rests on the pubis, and is immediately under the rectum. It is in part muscular by which it can expel its contents almost to the last drop. At its neck is a kind of sphincter to prevent the involuntary escape of urine, and at its posterior part it is placed by the ureters. To the bladder is attached a membranous pipe called the urethra, which passes through the penis, and by that means ejects the urine.

#### SUMMARY 14 The Fetal Colt

843. The reproductive system is one of the most important of nature's works; and, whether we consider the subject anatomically or physiologically we shall be convinced that the utmost wisdom and care have

been displayed to perfect the continuance of the species. The tender embryo, produced by the mutual sympathy of both parents, becomes placed in a situation the best adapted to its necessities and safety.

643. *Pregnancy and evolution of the foetus.* In the pregnant womb, the rudiments of the future animal are covered with epithelium from the neighbouring parts, and derive nourishment from a communication with the mother by means of the umbilical cord and farther by a surrounding fluid. In this state a speciality is observed in the foetal sanguineous circulation the whole of its abdominal blood passing through its liver (573), by which it gains a more early and perfect evolution to fit it at its first entrance into life for active exertions. Under these circumstances it daily acquires increase, until the distention is excessive becomes too great for the capacity when the muscular fibres of the uterus, powerfully assisted by the diaphragm and abdominal muscles, contract, and thus force both the foal and the membranes into the world.

644. *The new-born foal,* on its entrance into active life finds its organs of immediate necessity in a full state of capacity. Unlike the infant it is far from indigent, but can run and perform the common phenomena of an animal with dexterity and ease. Its powers are, however, not sufficiently developed to enable it to live independently. It has therefore a necessity for seeking support from the mother in the form of milk, and it may therefore be now considered in some measure as carnivorous. The milk is derived from a bag furnished with two nipples, having excretory outlets and valves to prevent the accidental loss of the fluid. These valves the instinct of the foal teaches it to displace by its nose. The milk of the mare being highly nutritious, its evolution rapidly increases and becomes fitted to perform all the more matured functions, and when fully able to coöperate its own wants, it vomitathes only with itself when the parent's care being no longer necessary the lactiferous secretion ceases.

645. *The period of gestation varies in different mares.* one hundred and two mares were observed by Townes of which 5 foaled on the 311th day 1 on the 323th 1 on the 328th 2 on the 333d 47 from the 340th to the 349th 25 from the 350th to the 360th 31 from the 360th to the 377th and 1 on the 394th day which gives a latitude of 85 days in the time of gestation

### SUBJECT 15. The Foot

646. *The foot of the horse present in their united functions a series of springs with great complexity of structure.* An unreflecting observer considers only the horny box, and perhaps attaches as little merit to its mechanism, as he would to a well turned wooden leg of a man. But a little examination will convince him that all the complexity all the admirable mechanism displayed in the assemblage of four fingers and a thumb, are here concentrated within this horny box and its appendages. As the parts which compose the hind and the fore foot do not materially differ a description of one foot will serve for the whole.

647. *On examining a perpendicular section of the foot and pastern (fig. 834)* there appears the coffin bone (a) the navicular or nut bone (b) the coronary or little pastern bone (c) the larger pastern bone (d) the back sinew or great flexor tendon of the foot (e) the same tendon sliding over the tin xul r bone (f), its termination or insertion into the bottom of the coffin bone (g), the elastic matter of the

tensile (h) the tin xul r bone (i) the frog (j) the horn (k) which includes the parts of the sensible foot the outer wall of the hoof (l) the elastic processes (m) the attachment of the extensor tendon to the coffin bone (n) and its attachment to the coronary bone (o) which completes the section.

648. *The coffin bone (fig. 835 a) adapts itself to the form of the hoof, or rather is adapted by nature to this eligible form.* The eminence in front receives the insertion of the tendon of the great extensor muscle of the foot, whose upper attachment is to the humerus or arm bone where it is fleshy but as it passes onward it becomes tendinous, expanding over every joint, both to prevent friction, and to embrace and give attachments to each bone by which a simultaneous movement of the whole limb is made. In the hinder limb this extensor and its two less adjuncts arise from the tibia and in part from the femur. In the sides of the coffin bone are attached the lateral cartilages, and around its surface are marks of the attachment of the laminated substance.

649. *The coronary or small pastern bone (c), articulates with the coffin at its posterior part, and articulating also with both these is the navicular or nut bone (f) whose attachments to them are effected by ligaments.*

650. *The hoof is convex, or rather as Clark observes, slightly truncated, and is a secretion as well from the vascular parts of the foot as from the skin as our nails are from the pores of skin called the quill.* The structure of the hoof is firm and fibrous externally plane and convex, but internally concave and laminated. The quarters are the lateral parts. As the horn approaches the heels it becomes soft, and is reflected upwards. The heels are parted by the horny frog (fig. 836 b) and without the frog on each side, the hoof reflects its fibres to form the bars which are seen on the under surface (fig. 836 c). In a

healthy foot (fig. 837) the heels are round, wide, and smooth (a a) the frog fully expanded (b); the bars or buttons distinct (c) the coria in the usual angle (d) the sole broad and concave (e). In a diseased foot (fig. 837), the heels are high and drawn together by contraction (a a), the frog narrow and filled with fissures from contraction and thrust (b) and the sole greatly shortened in its transverse diameter which is morbidly counterbalanced by the increased heights in the truncated form (c). When the hoof is removed, the sensible or fleshy sole (fig. 835 b) above which it sits.

immediately lies, presents itself covering the whole of the horny sole, except so much as is taken up by the sensible frog (b). This part is exquisitely sensible and vascular, and thus we learn why injuries to it from punctures produce such serious effects, and why very slight pressure from contraction of the hoof gives so much pain. The sensible frog and the sensible sole form the insensible frog and sole but when from pressure too much moisture, or other cause, the sensible frog, instead of forming horn, secretes pus or matter as we thrust, the structure of the whole becomes injured, and the horny frog, thus losing its support, gradually wastes and decays. It is, therefore, evident that no thrust can be entirely harmless, as is erroneously supposed. Above the sensible frog and sole is the great flexor tendon, or back sinew inserting itself into the vaulted arch of the coffin (fig. 835 e). This important tendon arising from its parent muscle above the knee, whose origin is taken from the triticeus and bina, in its passage unites with an assistant flexor, but which latter is generally distributed to the pastern bones while the *posterior* so called because it is perforated by the assistant flexor tendon, is inserted into the vault of the coffin. In the posterior extremities, the attachments of these two leading flexors, and a smaller lateral one, are from the femur and tibia.

651. *The sensible laminae.* Around the margin of the coffin bone it has been noted that there are

smaller tuberculations, to which about five hundred semi-cartilaginous leaves are attached. Each of these is received between two of the horny lamellæ which line the interior of the hoary hoof, and when it is considered what a vast surface of attachment is formed by these means, the strength of the union will not be wondered at. No common violence can separate these parts, and their use, in so many springs to support the actions of an animal, at once weighty strong and extremely agile, must be apparent. The vessels and nerves of the foot are derived from the metacarpal arteries, veins, and nerves, which pass behind the pasterns, when the main trunks divide to proceed to each side of the foot, and are ramified from thence throughout. It is a division of the metacarpal nerve on each side of the lesser pastern, or of the larger as osseous axis, which forms the *nerve operation*, now in vogue as a remedy for lameness.

#### SECT. V Diseases of the Horse.

6463. The diseases of the horse are so numerous and as important as his complicated structure, and the artificial state of his present mode of life, would lead one to expect. Until of late the treatment of these diseases was confined to the hands of ignorant barbers, presumptive grocers, or shoeing smiths; and the state of the animals was commensurate with the wretched treatment they were subjected to. The establishment of a school for the veterinary art has disseminated an improved practice and spread improved practitioners throughout the country, and we would earnestly recommend an application to one of established reputation in all cases of difficulty and danger. But as it is not always that such a one is within reach, to enable the agriculturist to have in his own hands the means of informing himself, or of being a check on others, we submit a concise view of the diseases of the head, neck, trunk, and extremities, preceded by some general observations.

##### SUBSECT. I General Remarks on the healthy and diseased State of the Horse.

6464. *Condition of horses.* Being in condition, in stable language signifies not only perfect health in generally but such an appearance externally as the philosopher would call unnatural, or at least artificial; while the amateur considers it as an essential requisite to the other qualities of the horse. This external condition is denoted by a sleek short, shining coat, with a degree of flesh neither bordering on fatness nor emaciation. Even in this sense of the term *condition* must be varied according to the uses of the animal. In the cart horse, provided there be sleekness of coat, looseness of hide, sound wind, freedom from grease or swelled legs with good digestion, a fulness and rotundity of bulk, instead of detracting from his beauty or impeding his exertions, will add to the one and assist the other. In the coach horse, the lackney the hunter and the racer, a different condition is expected, varying in different degrees from that of the cart horse. In both cart horse and racer, it is equally necessary that the various internal organs should be in a state to act uninterruptedly for the benefit of the whole; but, in addition to this, it is necessary to the racer that the greatest possible quantity of animal fire should be condensed into the smallest possible bulk; and that the absorption of all useless fat and other interstitial matter should be promoted by every possible means, as essentially necessary to unite lightness of body with full strength and elasticity. It is in the attempts to produce such a state in its full perfection that all the secrets of *training* consist; but whether a total departure from natural rules, by unnatural heat, deprivation of light, stimulating food, restraint from water and excessive clothing are best calculated to promote it, admits of much doubt: and it is to be observed, that the dawn of reason and science appears to be shining through the various of these darkened elements for even at Newmarket the system has lately much relaxed from its artificial rigour.

6465. *To bring a horse into condition.* not only should the purposes he is intended for be taken into account, but also his previous state. If he be taken up from grass with much flesh on him, it is evident that what is required is, to remove the soft interstitial matter it may be supposed he has gained by green food and to replace it by hard flesh, and also to produce a sleekness of coat and beauty of appearance. To accomplish these ends, the horse should be accustomed to clothing and the full heat of the stable by degrees only, and also by degrees only to the meditated change of food, which is best done by mashes. In two or three days a mild dose of physic may be given during all which moderate exercise only should be allowed as walking, but which may be continued two hours at a time. After the physic has set, begin to dress his coat increase his exercise and his food and accustom him to an increase of warmth. In four or five days time again mash him for two days, and give a second dose of physic, a very little stronger than the first (6564.) After this, still further increase his warmth, his exercise, and his food, by which his belly will be taken up, his flesh will harden, and his coat will begin to fall. A third dose of physic, or urine balls, &c. are only necessary in the training of hunters, &c. and even in these a gradual increase of exercise, rather long continued than violent, with proper food, will effect the end, if not so quickly, more beneficially to the animal. To bring a *lean horse into condition*, a somewhat different plan should be pursued. If from grass still mash him for a day or two, by no means stint him in his water and with his mash let corn be also soaked. If corn be spared or malted, it will produce flesh sooner. But even here, give the horse moderate walking exercise, and if he be not too much reduced, add a mild dose of physic to prevent his heels flying, or his getting hide-bound by the increased food: but if great emaciation forbid the physic, give him nightly an alternative. (*Vet. Pharm.* 6590. No. 1.) As his appearance improves, gradually harden his food and increase his exercise.

6466. *Diseased condition of horses.* What has been already said relates to that alteration from one state to another neither being an unhealthy one which custom has rendered necessary, thus a man in training for running or fighting and a man out of training, are both considered equally healthy. But there are circumstances, that produce a *morbid state of condition*, different from all these. It is common to hear persons say - My horse is *sadly out of condition*, and I cannot tell either what is the matter with him, or how to get him into better case. Various are the causes that may produce this: a sudden alteration of the food or temperature, or of habits altogether may become a cause. Removing a horse from grass to a heated stable, full feeding, and hard exercise, will often do it: therefore these changes should always be gradual. Bad food, as mow-burnt hay musty oats, beans, &c. likewise mineral waters, foul air &c. are frequent causes. Diabetes, or profuse staling is often brought on by these means, and the condition of the horse becomes greatly reduced. It is requisite, therefore, to enquire whether any of these errors are in existence, and to immediately remove them. But it often happens that the stomach has become relaxed and the hide become bound; neither of which readily remove, even though the original evil may be amended. When the relaxed stomach has produced lameness, treat the mouth as described under that disease (6466.) but the stomach itself must be principally attended to. First mash and give a dose of physic; when it has set, commence the treatment, if the horse be of a full habit, by a moderate bleeding and a nightly alternative (*Vet. Pharm.* 6590. No. 1 or 2.) But if he be not in full, put in low feed commenced by a daily *scow* (*Vet. Pharm.* 6591. No. 1 or 2), which will gradually remove the swelling within the mouth, and loosen the hide. A sudden cold applied to the skin often brings on a want of condition with *rust*. In which cases bleeding nightly alternatives (*Vet. Pharm.* 6590. No. 1. or 2.) with or without an assistant dose of physic, as the habit of the horse may require constitute the proper treatment. Worms form another cause of morbid condition, which are to be removed as described. (6473.) Excessive fatigue is also productive of a bad state of condition, which often proves very obstinate. Turning out to very good grass is the quickest cure, and when that is impracticable, stalling in the stable, or feeding with carrots, parsnips, beet-root, &c. will be good restoratives as medicines give tonic daily (*Vet. Pharm.* 6551. No. 1. or 2.) It will be only necessary to add, that in considering the state of a horse's condition,

the effect is apt to be mistaken for the cause, and the symptoms for the disease. Hides bound and lumps are not in themselves, any thing more than effects, or symptoms, the former being secondary and the latter being always, dependent on a diseased state of the stomach; both are, therefore, to be treated accordingly. Exactly the same will apply to all the other symptoms of morbid condition.

### SUMMARY. 2. *Inflammatory Diseases of the Horse.*

6401. *The inflammatory diseases of the horse are numerous, but his fevers are few, a febrile state being generally brought on by the inflammation of some important organ. Inflammation may be considered as general or diffused, and local or confined, and both seem to arise from an affection of the blood-vessels, and perhaps from a peculiar state of the blood itself.*

6402. *General or diffused inflammation constitutes fever or extensive inflammatory affection, and appears to consist in an increased action of the heart and arteries, accompanied with an increase of heat. In some instances where the fever is purely symptomatic, and dependent on the inflammation of some important organ, as of the lungs in the influenza, the circulation appears retarded rather than increased, from obstruction arising to its passage through the heart.*

6403. *Local or confined inflammation is also dependent on an affection of the blood-vessels, but confined principally to the blood vessels of the part affected. It is betokened by redness in the skin, tumour or swelling, heat, and tenderness, with pain. Inflammations, both diffused and local, are brought on by excitement, such as over-feeding, excessive heat, the reaction produced after cold and the reaction produced by increased exertion. These more extensive arise from injuries, the application of improper substances, &c. Inflammations arise in various ways but it is to be remarked, that in consequence of the very large circulatory system in the horse, his febrile affections rage higher and terminate sooner than in man. The usual termination of inflammatory affections in the horse is by resolution, effusion, suppuration, and gangrene. Scarce is met with all a common termination of inflammation in the horse.*

6404. *Inflammation of the brain (cephalitis), brain fever (phrenitis), madness, and sleep.* There are few diseases more likely to be mistaken by inexperienced farmers than this it is not to be wondered at, therefore, if indifferent persons should be led into error by it. It appears in two forms, a violent frantic one, and a sleepy lethargic one and the latter appearance is also common to a disease not dependent, as this is, on idiopathic inflammation of the brain, but on a paralytic affection of the stomach, and the lungs.

6405. *Inflammation of the stomach, bowels, and lungs.* These latter affections, however, may be distinguished from the former by attending to the colour of the eyelids, nose linings, mouth, &c. which in stomach staggers, are usually more yellow than red whereas, in sleepy staggers, they are more red than yellow. Inflammation of the brain shows itself in general cases, by disorientation to food and motion drowziness, accompanied by a heaviness and closing of the eyelids, with moisture and redness of them and also of the linings of the mouth and nose. Sometimes these symptoms increase until the horse becomes comatose, and after a few fruitless struggles, he sinks to rise no more. In these cases the pulse is apt to be oppressed, instead of increased, but more frequently after the first stages he becomes furious, plunges about, and is vicious to himself and others, approaching to a state of madness in which state he continues till he sinks from his own exertions, when he rises again to renew his violence.

6406. *The cause of staggers may be various: the immediate are either an original accumulation of blood within the brain, or the transmission of the inflammation of some organ to the brain. As a remote cause it is often brought on by too full feeding, without sufficient exercise, and particularly in horses at one time working very hard, and at another suffered to remain inactive but which horses, whether used or not, are equally sad. Sudden cold violence, &c. may bring it on.*

6407. *The treatment of staggers should be begun by abstracting a very large quantity of blood promptly by opening both jugulars, and letting the horse bleed to the amount of ten or even twelve quarts repeat, if necessary, the same at the distance of hours. After the first bleeding, back rubs, throw up a laxative (Vide Phlegm 6064), blister the head, promote a current of free air in the stable, and treat altogether as directed under other febrile affections.*

6408. *Lacked jaw, stag-cold, orismus* arises from cold, excessive fatigue sometimes perhaps from worms, but more often from a wound of some part, as prick in sheening &c. Each wound is seldom in a recent state, has after two or three weeks subsided, sometimes after it has healed even, it follows locking, relapsing, and sticking frequently and is preceded by a flabby unhealthy state of the ground. It is not always produced by an open wound, it is sometimes consequent on a bruise, strain &c. and is sometimes brought on by cold, violent exertions, &c. &c. It appears as an affection of the brain, which transmits its morbid excitations, particularly to the nerves attached to muscles, by which they become cramped, or may be considered as in a high state of action, giving the horse a peculiar look of energy as though immediately stopped from full speed, with his nostrils extended, his head raised and nose carried forward. His legs straddle wide, and his tail is cocked and quivers, as after violent exercise. The jaws will now be found if not closed, yet nearly so, when he is called jaw set.

6409. *The treatment is not often successful but, however it is sufficiently frequent that it is so, to deserve the utmost attention. Blaine informs us that enormous bleedings have succeeded but he places his principal dependence on the application of cold by the means of ice, or of constant dashing with cold water with an active blister applied the whole length of the spine. Balls of camphor and opium, to the amount of two drachms of each, may be given every three hours. If any room remains in the mouth, the ball may be passed up by means of a stick, or it may be given as a drink by means of a syringe and even when the mouth is entirely closed, he informs us we may give a drink by the nostrils. Moorcroft used cold also. Fearon, on the contrary has experienced benefit from a bath heated to ninety degrees, and kept at that temperature for three hours. While recommending camphor and opium Wilkinson of Newcastle has been very successful by keeping up heat and stimulus over the skin in general by means of newly stripped sheepskins put on hot. Perhaps if the body were previously rubbed with oil of turpentine one part, and common oil two parts, it might assist Wilkinson's plan. When lacked jaw arises from sticking, it might be prudent for a veterinary surgeon to dissect down on the nerves of the tail, and divide them; and when from docking, it would be advisable at once to cut off another portion of the tail which operation, in both instances, would afford a moderate chance of curing the animal. It is necessary further to remark, that it is of great consequence that the bowels be kept free from feces, by raking and douching. With regard to the latter they are very important in this disease, as a medium, commonly the only one, of giving support. A horse has been kept alive on nourishing clysters alone for seven or eight days. (Vide Phlegm 6064.)*

6410. *Catarrhal fever, epidemic catarrh, influenza, distemper cold, morbofundering* &c. These names belong to one common disease, which often is a very variable entity in this form in the spring of some years, more than of others. It is not contagious, like the more malignant form, but is brought on as an epidemic by the same causes being applied to nearly all subjects alike which are alternations of heat with cold, moisture, and dryness, &c. in crowded cities and large towns it is more prevalent than in more open situations, and it is more frequently found in the young than in aged horses. Where it does exist as an epidemic it is brought on by an accidental cold taken. It is of great consequence to distinguish it from pure inflammation of the lungs, with which it is very apt to be confounded; and which mistake is often a fatal one, both the treatment being in some essential particulars different. Inflammation of the lungs commences by a short cough, without much other disturbance to the health than the pain it gives the horse to cough; but which is often so considerable as to make him stamp his feet while coughing. If it turns to the dangerous cough early it is not a hollow harsh-sounding, and distressing cough of this kind. If he continues unconscious, it is principally from a sore throat, which is very common

in distemper, but by no means common to pneumonia. The sore throat in distemper gives the horse a disinclination to refuse his food, or he chews it and lets the quid fall without swallowing it. His refuses water, particularly if it be placed on the ground. His cough is quick, short, and usually sounds more moist than harsh and dry, but though common this is not invariably the case. His eyes are heavy and moist, his breathing is quickened, and his ears and legs are alternately hot and cold. His nose on looking into it is redder than usual, and sometimes has glands as well submaxillary or jaw glands, as his parotid or virus, are tumid. On the second or third day excessive weakness comes on, the cough becomes more painful, the pulse is quickened, and the nose begins to run. After which the horse either runs off the disease by this suppuration, or it goes on to destroy him by the height of the fever and degree of weakness produced, or by suffocation from water in the chest. Now and then, although recovery takes place an obstinate cough is left; and in a few cases the disease terminates in glanders.

6435. *The treatment* may in some cases be cut very short for as in almost every instance a shivering fit begins the disease, so when many horses are in a stable, and the disease is very prevalent, those who have not been attacked should be washed, and the room in which such an attack does take place, give of sweet spirit of nitre, or when not at hand of spirit of horsethorn, an ounce, in a pint of sound ale. Exercise the horse briskly then well hand rub him, clothe him warmly and it is more than probable that the disease will be cut short. But should it proceed, or should the disease have gone on unnoticed to the appearance of the symptom detailed begun by bleeding moderately if the horse be not already waked, or if there have not appeared the running of matter from the nose. If there have, the bleeding had better be dispensed with, unless the fever appear, from the quick full pulse and refusal of the inner surface of the nostrils and eyelids, to be still so considerable as to require it. In which case we must not be deterred from one moderate bleeding and which, if the febrile symptoms do not abate, may be even repeated. It will, however in general cases, be advisable to avoid bleeding after the second day of the attack or after the discharge has appeared from the nose, or after considerable weakness has come on. In all cases a warm cool temperature is essentially requisite hot stables or hot clothing is very pernicious, but particularly the former. A hood is not improper over the head, because it encourages the running to make an early appearance and for this reason a warm mash may advantageously be hung round the neck three or four times a day. Before the discharge commences, give night and morning the fever powder (Fet. Pharm. 6578. No. 1. or 2.) in a mash or drink after the running has come on or as soon as the weakness has become considerable, give night and morning either of the fever drinks. (Fet. Pharm. 6578. No. 3. or 4.) Malt mashes, when the weakness is great, are proper. Other times bran mashes with plenty of chilled water are best. To relieve the throat, rub the outside with mild liquid blister (Fet. Pharm. 6563.) and if the weather be warm enough to allow it, two or three hours turning out in a field each day is proper. Green meat in the stable, when it can be procured, should likewise be given.

6436. *Malignant epidemic, murrain, or pest.* Now and then the distemper or influenza assumes a character of uncommon malignance which is hardly not frequent here, but not unfrequent in continental countries sweeping off a third of the horses and lime, without any means being found sufficient to arrest its progress. In these cases it is highly contagious, attacking almost all the horses as well as cattle within its sphere of action or which communicate with each other. Dr Laidlaw and Osmar English writers of established reputation, noticed the appearance of this disease long ago, and their descriptions are very different from the milder kind noticed (6435.) but in degree. The throat is intensely sore and the mouth ulcerated, the glands of the head swell, and sometimes these and other parts suppurate and burst. The matter from the nose is bloody and the stench intolerable the weakness is also peculiarly great, and shows itself early.

6437. *The treatment* recommended by Blaine is the early use of malt mashes; even ale is indispensable. Green meat should be allowed, and a very cool stall is necessary, having a free communication with the open air. As medicine three doses are necessary every day of the malignant epidemic fever drink (Fet. Pharm. 6582.) half a pint of yeast with a pint of ale has been given with good effect, three times a day also, to prevent the infection from spreading, fumigate the stables and all the outhouses with the preventive fumigation. (Fet. Pharm. 6583.)

### SUMMARY. 3. Diseases of the Head.

6438. *Epilepsy, merrima, stury or turnick*, are epileptic attacks of greater or less violence, and which are apt to be confounded with the accidental strangulation that sometimes takes place, from a collar too tight, or from driving a horse hard up hill, &c. The epileptic fit makes its appearance by a sudden stop if the horse be in action he shakes his head, looks wild and irresolute, but after some time he proceeds when more violent, he suddenly falls down, is convulsed, jerks and stales incessantly and remains some time before he recovers. The disease, like tizzen, is generally the consequence of too full a habit and is, therefore, best relieved by bleeding, and a more moderate diet and, where it is convenient, a run at grass should be allowed to alter the habit.

6439. *The diseases of the horse's eyes* are not numerous, but they are very destructive. The principal are ophthalmia and gutta serena.

6440. *The ophthalmia, laminitis or moon blindness*, is a very peculiar disease among horses, affecting their eyes generally about their full growth, but sometimes later, and seldom earlier. It is but little known among mules and asses, and unknown in oxen and sheep. It does not, however appear to be a disease natural to the horse, as wild ones, or even those little subjected to artificial restraints, are not observed to be subject to it but among others, it becomes so common as to have the tendency handed down in the breed, the progeny of some stallions being more prone to it than others. It is often very sudden in its attack, the eyelids being found swelled and almost closed to avoid the light they are also very red within, and the lars is half drawn over the surface the tears flow down the face perpetually and the whole head is hot; now and then these appearances come on gradually. The suddenness of the attack makes the complaint to be attributed to accident, as blows, hay-seeds within the eye, &c.; and it is frequently difficult to get the owner of such a horse to believe that a constitutional attack, as it usually is, can come on so suddenly. Sometimes as it comes on quickly so it goes off, the eye, from being opaque and milky, in twenty-four hours becoming clear and almost well. When such an attack has taken place even if nothing be done, the horse sooner or later amends, and the eye or eyes — for it is sometimes one, and sometimes both that are so attacked, — become again clear and well, and remain so an indefinite period from five or six weeks to as many months. Another attack, however sooner or later follows, to which others succeed, each leaving increased milkiness on the outer coats and some dimness within the pupil, either speak like or diffuse; and finally the horse becomes blind from cataract. When one eye goes blind totally before the other it is often the means of preventing the future attack on the remaining one which has given rise to a custom of putting out one eye to save the other and which has succeeded. As this is a constitutional disease, brought on by artificial habits, as over-exertion close unhealthy confinement, and heating food; so it is clear the abstraction of all these are necessary to remove the complaint, and to prevent a recurrence, but particularly the close, dark, and unventilated state of the stable should be avoided to, as well as the use of the litters which retain the volatile alkali of the urine, and irritate the eyes most injuriously. The food should be mild and cooling, and the exercise moderate, but long continued. Under the height of the attack, however, rest is advisable, with moderate light, which may be still further moderated by keeping over the eye or eyes a thick cloth wet with guaiac water (Fet. Pharm. 6575.) Sometimes one quart of vinegar to three quarts of water has been found a useful application and whichever is used, the eyes and eyebrows should be kept continually wet with it, which

by exciting evaporation will keep the part cool. A seton may be introduced under the eye or jaw. In some cases, blistering the forehead of the neck is found useful; but in every instance bleeding is proper, which should be repeated until the disease is cured. When the horse is very full and gross, phlebotomy and blisters assist the cure. When blistering is used in any part near the eye, the greatest care is requisite to prevent the blistering matter from being rubbed into it. A very peculiar ophthalmic affection is also sometimes encountered, particularly in the horses of hot climates, by the entrance of a filaria or thread-worm into the globe of the eye, which swimming about in the aqueous humour, eventually occasions violent inflammation. The cure consists in letting out the aqueous humour with a lancet, when, the filaria escaping with the fluid, recovery follows.

641. *Grains or ophthalmia*, so called from the parallel glossy appearance of the eye, arise from a paralysis of the optic nerve. As the eye is not materially altered in appearance, a horse often becomes blind without his being noticed until his cautious stepping, quick motion of his ears, &c. give notice of the case. On examination it will be found that the pupil remains dilated, however great the light, and the eye is immovably lost. In the very early stage, blisters to the forehead and stimulants to the eyes (as *white vitriol* or *drachm.*, *water four ounces*), may be tried, but with slight hopes of success.

642. *Pole evil*. This complaint commonly requires the attendance of an experienced practitioner, but the prevention is often in the power of owners, and others about horses. And to this point we shall particularly direct their attention. Pole evil is commonly the effect of accident. Reported small blows of the manege, or continued pressure from hanging back on the halter &c. will, if not remedied, produce swelling at the nape of the neck, with some tenderness. In this early state, if the collar be removed, and the part be kept continually wet with vinegar and water the swelling will often disappear; but if, in spite of this, it proceeds to suppuration, let a vent be made for the matter by a seton (637) so that it may readily discharge. Introduce nothing but good healing, but encourage a free discharge, and it may yet heal of itself. When such is not the case, the disease attacks the ligaments, sinuæ, and the matter burrows under the skin and muscles, when a seton must be introduced from the opening above and should be brought out at the bottom. The seton should be then daily wetted with the liquid blister (*Vel. Pharm.* 638.) Should this plan fail, escharotics will be required in the form of the *scalding salivary*. (*Vel. Pharm.* 638.)

643. *Strangles, distemper or fever*. This disease has been likened to the human measles because it usually attacks every horse, and most of them at a young period between three and five years. It is fortunate when it attacks colts at grass, as it seldom occasions inconvenience which has led some persons into error by turning their horses out as soon as attacked but it is not found that stabled horses, thus turned out, pass through the disease more mildly but the contrary except the disease exists under its very mildest form. White has conjectured that colts breeding the strangles while at grass are afterwards exempt from glanders, but this wants confirmation. Prosser has also affirmed that inoculation by the matter of strangles is good because it mitigates the complaint, and renders the horse not liable to any future attack but the practice has never gained ground. When the strangles occurs in the stable and now and then also in the field, it proves a severe disease, and shows itself under the appearance of a cold with cough, sore throat, and swelling of the glands under the jaw, or behind and under the ears. Sometimes there is not much swelling, and the tumours break inwardly, and nature effects a cure at others they break outwardly, and the disease runs off that way and sometimes the swellings disperse either by nature or art, which breeders think unfavourable, as they suppose it renders the animal liable to a future attack, but many so treated pass the remainder of their lives without more affection.

644. *The treatment of strangles*. When the swelling fingers, and neither comes forward nor recedes, poultices are preferable to fomentations, which, by leaving the horse wet, promote evaporation and produce cold. Poul recommend blisters to the part, as the best means of promoting suppuration. The horse should be kept very cool, and bran mashes with warm water should be his principal support, unless the complaint last long, and produce much weakness, when malt mashes should be substituted. Bleeding is only advisable when the early symptoms are violent, as heaving at the flanks, extreme soreness of throat, with much swelling around it, and considerable cough in which case bleeding and fever medicines are proper.

645. *Fever or fever*, is supposed to be a relic of the latter complaint, and it does appear now and then that after the strangles the parotid or viva glands do remain enlarged (645.) which occasions the disease in question. resolution may be attempted by mercurial frictions; suppuration should be avoided, otherwise the gland may be destroyed.

646. *Disease of the mouth, lampas*. All horses, but particularly very young ones, are liable to enlargement of the rugæ or ridges of the palate, dependent not on any local disease confined to the part itself, but occasioned by an affection of the whole passage of the mouth, throat, and stomach. It is usual to attend to the part only which is sacrificed or burnt to little purpose, when a mild dose of physic, or gentle alteratives, would prove more certain expedients to which may be added rubbing the rugæ themselves with bay salt, or with vinegar.

647. *Brillie sores*. When the bit in colt breaking, or in hard-pulling horses, has hurt the bars, care is requisite to prevent the horse becoming vicious. Touch daily with egg-yellows, and cover the bit with leather unless total rest can be allowed.

648. *Diseases of the teeth* are fully treated of under the anatomical description of the bones. (630.)

#### SUMMARY 4. Diseases of the Neck.

649. *Moleous affections* are brought on usually by pressure from a saddle with too low or narrow a saddle-tree, and what has been said both with regard to prevention and cure on the subject of pole evil, will equally apply here also. (642.)

650. *Sore throats* is common to horses in colds, in influenza, and in strangles. (643. 644.) It is discovered by the horse chewing his hay but instead of swallowing he drops it from his mouth, or, as it is called quids it. He likewise shows a disinclination to drink. In every case, the horse finds great difficulty in reaching every thing that stretches his neck downwards or upwards his water therefore should be held to him, and his hay should be pulled for him; omission of these services greatly aggravates the sufferings of horses labouring under sore throat.

651. *Swelled neck*. A very serious swelling sometimes follows on bleeding with a rusty or poisoned lancet, or fleam, and sometimes also from causes not apparent. (657.)

#### SUMMARY 5. The Chest.

652. *Inflammation of the lungs* is a disease to which the horse is peculiarly liable; as we might a priori suspect, from the vast dimensions of his circulatory system, and the vast alteration from a natural state to which we subject him, and thereby increase his pulmonary circulation.

653. *The causes* are those derivatives remotely but the immediate attack is generally brought on by sudden cold, acting on a heated surface; and thus it is that knockers and collar-makers in frosty weather suspect a flux of horses that die from this disease. Hard riding is a very common cause, and high feeding also, it often commences slowly, a hard dry cough has been slightly noticed, but which has continued so close for twenty three days; gradually however the cough appears to give the horse pain; he occasionally shivers, and his ears and feet feel colder than the rest of his body; he heaves at the flanks, and the lining of his nose is found to be much more red than usual, in the worst case it is seen of a purple hue; the

inside of the eyelids also are tinged with the inflammation. The appetite now becomes affected, and although there is not much apparent pain, except when the horse coughs, yet there is much anxiety of maintenance present. The pulse is usually small but quick. If in this state the horse accidentally or erroneously be taken out and subjected to considerable exertion, it is almost always fatal to him. It likewise happens that this complaint is sometimes mistaken for distemper, and, from a fear of profuse bleeding, the only remedy that is to be depended on is omitted, and the horse is lost. At the veterinary college, in these cases a small dose of doses is given every six hours, and after being bled and rowelled, the horse is turned out in the open air, and it is affirmed that many recover from this treatment. Certain it is, that the stable in which a horse is placed in this disease can hardly be too cool, but when entirely turned out, his feet and legs cannot conveniently be hand-rubbed, or bandaged up to promote circulation, neither can we blister a horse when turned out, so conveniently and on blistering we depend as the second source of cure.

6454. The treatment is to be commenced by attempts at lessening the action of the arterial system by early and large bleedings as seven or eight quarts from a large horse, and which should be repeated in five or six hours if he be not relieved in his breathing. Immediately rub into the brisket on the chest, and behind the fore legs, the blister (*Vet Pharm.* 625 No. 1). Give half a dose of phlegm, and assist it by mashes and warm water which, if not readily taken, horn down. Back rake also, and throw up the laxative clyster (*Vet Pharm.* 626). Avoid all exercise, clothe moderately, allow a free circulation of cool air through the stable, and rub the legs frequently and a ben not under this process keep them bandaged up to the knees with hay bands or woollen cloths. When the bowels are opened, give the fever drink (*Vet Pharm.* 626) three times a day. The terminations of this complaint are various. It is not uncommon for the horse to appear better, to eat and to drink, and to excite every hope of a perfect recovery, but on some sudden exertion he falls down and expires. On examination after death it is found that effusion of a large quantity of serous fluid has taken place in the chest.

6455. Thick wind is another termination of pneumonia, by leaving the bronchial passages charged with coagulable blood, and the horse is confined in the stable, with mild mercurial phlegm, form the best mode of treatment, but frequently the cough results all these, and terminates in broken wind.

6456. Roaring is also a termination of pneumonia, in which case the lungs are not affected, but coagulable blood, under the name of coagulable lymph remains in the tracheæ or windpipe and obstructs the free passage of the air by means of which the roaring noise is made. It is in vain to expect a cure blustering the throat sometimes slightly relieves it.

6457. Chronic cough is also a termination of pneumonia, and appears dependent on a peculiar irritability the disease leaves in the bronchial passages, which are found afterwards incapable of bearing any sudden alteration of temperature thus horses with this kind of cough are excited to it as soon as the stable door opens, and by every exertion by drinking, by eating, and, in fact, by any thing that alters the situation of the body or is new to the part. But, besides pneumonia or inflammation of the lungs producing it, it is often brought on likewise by green feed &c. which, by weakening the stomach, impoverishes the blood, and thus impairs the lungs which are fed by that blood. Worms also by the same means are a cause of chronic cough. It is thus that we expect to derive benefit by medicines acting on the stomach. Green food is often found useful but particularly carrots. The hay should be excellent in quality and small in quantity and it will be found that soiling in the stable but particularly a course of carrots forms a better plan of treatment than turning out. If worms be suspected, treat as under that head. (6478). Formulas of chronic cough balls are seen in the *Vet Pharm.* (656).

6458. Broken wind is also sometimes brought on by pneumonia and sometimes by occult causes. It is often occasioned by over-exertion after full meals, in which the lungs become permanently weakened, perhaps ruptured, in their air cells. Inexperienced persons find some difficulty in detecting broken wind from other chest affections, as chronic cough, occasional colds, &c. &c.

6459. Cries of broken wind. The cough which accompanies broken wind is a short deep hollow grunting noise, and the short grunting expiration is peculiarly excited by turning a horse quickly round, striking him smartly with a stick at the same time, which often produces the deep sound without the cough, and which is so significant as never to be mistaken when once heard and attended to. But the principal peculiarity arises from the beating of the flanks, which operate rather by three efforts than by two as usual. In the first, the air is drawn in in the usual manner and the flanks fill up as in common but in the next the filling of the flanks is by no means natural for it is not done by a gradual sinking of the sides but it takes place at once, with a kind of jerk as though the horse were sighing, and then a third effort takes place by a more slow drawing up of the muscles of the belly and flanks, to press out the remaining air. Broken wind usually destroys the fecundity of the mare and hence argues permanent alteration of structure. It is also always incurable, but horses may be rendered very useful that have it by feeding them very cautiously but with their food much condensed in bulk. Little hay should be allowed, and that little should be wetted, water in any other way should be given but sparingly for which they are however very greedy from which circumstance, as well as that they are peculiarly silent, we learn, that the vitiation of the lungs is either aggravated by the deranged state of the digestive organs or which is more probable, that the digestive powers become weakened from the state of the lungs. In some few cases a partial rupture of the diaphragm or nistral has been observed in broken wind.

6460. Diseases of the belly. Inflamed stomach seldom attacks the horse as an idiopathic affection, but it is not unfrequent for the stomach to become inflamed by mineral poisons as well as rendered inert by vegetable ones. Over-distention may also inflame it.

6461. Mineral poisons inflame the stomach acutely and produce excessive distress, and cold sweats, the animal lies down rolls, gets up again, looks short round to his ribs, stamps with his fore feet, and his pulse beats quick and short. When arsenic, or corrosive sublimate have occasioned the malady, a viscid mucous distill from the nose and mouth, and the breath is fetid. When copper in the form of vitriolic salts or verdigris has been given, to the foregoing symptoms are usually added ineffectual attempts to vomit. Immediately the poisoning is discovered, pour down two ounces of sulphurated potash, in a quart of water or in the absence of that, an ounce of common potash in the same quantity of water, or when no better substitute is at hand, even strong soap-suds are admissible. Mineral poisons have also another mode of acting, and are often received into the constitution, neither by design to do mischief, nor by mistake but are purposely given as remedies. In this way both mercury and arsenic are frequently given for worms glanders, &c. &c. In daily doses, which when even of considerable magnitude, occasion for many days no inconvenience all at once, however, the constitution becomes fully saturated with the poison, and although better diffused throughout the blood, it now appears to return and act on the stomach to the great surprise of the owner. In these cases the symptoms are not usually so violent as in the former instances, but they are equally fatal. A similar treatment with the one already prescribed is necessary, and as soon as the first symptoms are abated, give laxatives. In all these cases, large quantities of linseed tea should be horned down, the back should be raked, and clysters thrown up blood should be taken away plentifully. As a preventive to this latter mode of poisoning, whenever mineral agents are used, it is prudent every five or six days to stop a while, and then recommence, by which the constitution will rest with the previous quantity.

6462. Reluctation is also another mode of poisoning, and though not equally injurious to the stomach, it often proves distressing, and sometimes fatal. Whenever therefore, mercurials are given, carefully watch the gums, and as soon as they look red, and the horse quids his hay, give him a solid purge instead of his mazarine.

6463. Stable poisons also inflame the stomach but by no means in an equal degree with the mineral poisons. It is supposed that it is the inflammation they raise that proves destructive, but by an effect

communicated through the stomach to the nervous system. Digitalis purpurea or foxglove, *Thapsus* *fulgens* of yew, *Gelsemium* *sempervirens* or winter dropwort, *Actea rubra* or water hemlock, *Phoradendron* *aquaticum* or water pennywort, *Asium mandibulum* or common hemlock, are all poisonous in a high degree to horses, and may be taken accidentally by the animal as food, or given injudiciously as medicine. Nicotiana or tobacco, and the vegetable acid or vinegar, are also poisonous, and are sometimes productive of injurious consequences by over-doses, when intended as remedies. It is little known that a pint of strong vinegar has destroyed a horse. As we cannot remove the matters from the stomach, we must endeavor to neutralize their effects by alkalis and demulcents, as oil, butter &c. Thus, when narcotics have been taken, a draught of sulphuric acid or oil of vitriol may be given in a quart of ale, or six ounces of vinegar, with six of gin, and a quart of ale, may be tried. An excellent domestic remedy might be found in two ounces of flour of mustard mixed with ale or other fluid.

6461. *Stomach staggers.* This peculiar complaint, which is even yet but little understood, appears dependent on a particular state of stomach acting on particular foods; and not on what is taken in acting on the stomach, as was supposed by Coleman, White, and others. From later communications of White, he also now appears to consider it as originating in "a peculiar state of stomach." Blaine appears always to have characterized it as "a specific inflammation of the stomach." It appears among horses of every description, and at grass as well as in a stable; and there is reason to think it epidemic, as it is prevalent in some seasons more than in others. It may perhaps, be regarded now and then as endemic also; under which circumstance it appears confined to low wet situations, where long matted grass is abundant, and where noxious aquatic plants mix themselves with the graminæ. When it occurs at grass, the horse is found stupidly dull or asleep with his head resting against something. This has sometimes the disease to be called the sleepy staggers and it has often been confounded with the pnenia, or inflammation of the brain. (6462.) In the stable the horse drowses, and rests his head in the manger. He then wakes up and fails to eat, which he continues to do until the digestion of the stomach becomes enormous; for the peculiarity of the complaint consists in the total stop that is put to digestion, and the uneasy state of the digestion consequent to such indigestion appears to deprive the horse, and by a morbid excitement to force him to take in more. In this way he continues eating until the distention prevents the return of the blood from the head, and the animal dies apoplectic, or his stomach bursts with over-distention. More frequently however the stomach becomes flabby inert, and paralytic, and after death presents marks of inflammation toward the pylorus.

6463. *The treatment.* When recovery has taken place, it has occurred only when the disease has been very mild, and has been assisted by stimulating the stomach into action by purgatives, at once active and invigorating, as an ounce of aloes dissolved in half a pint of gin. When a horse of extreme value is attacked, croton oil might be tried to the amount of 50 or 75 drops in two ounces of tincture of aloes. Warm water in small quantities, or mixed with common salt, should be frequently passed down. Remove every stable; rake, cypher and hand-rub and, if the determination to the head be extreme, bleed, other wise avoid it.

6465. *Inflammation of the bowels, enteritis or red colic* is a very distinct disease from the gripes, colic, or fret, with which it is, however very apt to be confounded to the destruction of many horses. The peritoneal inflammation of the bowels, the one here treated on, is an affection of their outer covering.

6467. *The causes are various.* It is not unfrequently brought on by a sudden translation of cold after great heat, as swimming during bunting, or from the removal of a horse from grass at once into heated stables neglected gripes, or long-continued coarctiveness, excessive riding and the immediate drinking of cold water have brought it on. It begins by restlessness, loss of appetite, and some uneasiness the mouth is hot and dry the inner membranes of the mouth nose, and eyelids are often redder than natural. As the disease advances the pain, before now violent, now becomes so as to force the horse to his dooryard and rise again frequently and when very violent, he kicks at his belly or looks round at his sides, pawing his flanks very frequently. The pulse is usually small, quick, or hard; sometimes it is more full and small, but always hard. Breathing is quickened, and the flanks heave the extremities are alternately hot and cold, but continue longer cold than hot and the animal is inactive sometimes pain may force away a few hardened balls of feces, but the principal contents are retained. Blaine has given the distinguishing features between this disease and colic, under which head we have stated them.

6468. *The treatment* must be active and immediate, or a fatal termination may be expected. Begin by abstracting a considerable quantity of blood from a large horse to the amount of seven or eight quarts proceed to back-rub; throw up a large cypher of warm gruel. Give by the mouth, if the expense be not considered an object, a pint of castor oil, mixed by means of the yolk of two eggs, with half a pint of broth or gruel. If the expense be objected to, give olive oil instead, following it up in half an hour by a gradual draught in which six ounces of Epsom salts have been dissolved. A sheep-skin, immediately as it is removed from the sheep, may be applied to the belly which should first be well rubbed with the stronger liquid blister (*Vol. Pharm.* 6562.) In four hours repeat the bleeding if a considerable improvement have not taken place, and if the bowels be not unladen, give more oil, and cypher frequently having first back-rubbed. Avoid exercise, first hand rub and afterwards wrap up the extremities to the knees. As a clear passage for the dung is found, the symptoms subside, and the animal slowly recovers; but he must be fed at first very sparingly.

6469. *Inflammation of the inner surface of the intestines* is, in some measure, different from the former which, as before stated, is an affection of their outer covering whereas this is usually confined to their villous surface, and may be brought on by superpurgation from over-strong physc, or from mineral salts being taken in, particularly mercurials which often exert more influence on the bowels than on the stomach.

It differs from the former in the symptoms being generally accompanied with purging, neither is there usually so much pain or uneasiness present, nor such cold extremities; but where from the violence of the inflammation these symptoms are present, bleeding to the amount of three or four quarts is a proper preliminary but can hardly be with propriety continued. The same stimulants to the outside of the belly should be used as in the last disease, but here, warm general clothing is recommended as well as warmth in the stable, as also hand-rubbing to keep up the circulation in the extremities. Give osmargent drink (*Vol. Pharm.* 6562. No. 1. or 2.) with a pint of boiled starch every three hours, and give the same by cypher with two quarts of pot liquor or three liquor free from salt.

6470. *Spasmodic inflammation of the horse's bowels* is happily not very common, but now and then appears, and is then called by farmers malden grasse they mistaking the morbid secretion from the intestines, for the fat of the body melted down and passing off thus but spasmody is a peculiar inflammation of the inner surface of the intestines, not contiguous as in the former, nor epidemic, nor exhibiting a putrid tendency; but is peculiarly confined to a diseased increase in the mucous secretion, yet very different from simple diarrhoea, which is a mere increase in the peristaltic motion, by which the common aliments are quickly passed through the intestines, and ejected in a liquid form by an increase in their watery secretion. Whereas in the spasmody of the horse the mucous of the intestines separates from them in large quantities, and comes away with the dung surrounding it; but when it does not pass in this way it appears in mucus than like sudden loath, or in stringy secretions like mucus of hot feeding in water; sometimes there is a little bloody appearance. The usual symptoms of fever are always present, but not in a very high degree.

6471. *The cause* are cold, over riding, and not unduly strong solid substances within the intestines; change of food has sometimes it, and now and then superpurgation from strong physc.

6472. *The treatment* is to bleed moderately and give, as the first internal remedy, six ounces of castor oil, which will relax the fecal strata considerably; afterwards administer the

following — *Powdered opium, a drachm; powdered opium, a scruple; Liquid arrow-root, eight ounces.* Should this not check the evacuation, and should it continue as mucous as at first, again give castor oil, and then follow it up by either of the drinks directed for the cure of scouring or looseness. (*Vet. Pharm. 428*.)

6474. *Diarrhoea or looseness.* This complaint originates in an increased peristaltic motion of the intestines, with an increase of their watery secretion, and is distinguished from dysentery by the purging being complete from the first, and seldom occasioning much fever or disturbance in the general health, unless exceedingly violent. The stools are merely solutions of the aliment, and unmarked with membranous films as in dysentery or mottled greases. It sometimes succeeds to over-streng physac at others the food itself enters into new combinations and forms a purge. Some horses have their bowels constantly weak, as buck-sized small-carbonated ones, where the mechanical pressure hurries the contents forward. Salt marshes and sea water will purge horses violently sometimes. In violent cases, horn down liquid starch, and throw up the same by clysters. Give astringents (*Vet. Pharm. 5562*, No. 1) two or three times a day keep the animal warm and quiet. In the milder cases and in habitual scouring change the food. The change should be generally from one more moist to one less so, as beans, &c. Barley will sometimes stop looseness; malt usually increases it. Buck-wheat is often a check to habitual diarrhoea. Silicious sediments will be found in the *Vet. Pharm. (5562)*. Repeat either of these night and morning. Give but little water and that little warm.

6475. *Colic, flatulent or spasmodic*, called also *gripes, fret or guttion*, is an important, because a frequent, disease, and because it frequently destroys either quickly by its irritation or by its degenerating into the red or inflammatory colic, when improperly treated or long continued. It is usually very sudden in its attack.

6476. *The causes of colic are not always apparent.* It is sometimes occasioned by intestinal worms, which accumulate to a great size, remaining for years in the cells of the colon, until some accidental displacement occasions an interruption to the peristaltic motion. Cold in its various forms is a parent of colic; but under the form of cold water given when a horse is hot it is most common. In some horses it is so frequent as to become a constitutional appendage.

6477. *The diagnosis is determined by the nature and inflammation of the bowels are gained, according to Blaine, by attending to the following circumstances.* — In gripes the horse has violent fits of pain, but they remit, and he has intervals of ease. The pain in red colic is more uniform and less violent. In gripes, the pulse is, in general, natural. In red colic it is quicker than natural, and commonly small. The extremities are not usually cold in gripes. In red colic they usually are. In gripes, the horse attempts to roll on his back, which in red colic he seldom does. There are no marks of fever with gripes, as red eyes, inflamed nostrils, &c., but in red colic they are always present. When spasmodic colic has continued some hours, it is always proper to bleed to prevent its ending in inflammation. bleeding in the mouth is quite useless. Back-rake and throw up clysters of warm water one after another as fast as possible, which often overcomes the irritation. La Fosse recommends a curious remedy but as it can always be obtained, and has the machine of long expense it may be tried. An onion is pounded and mixed up with some powdered saffron in default of which use powdered ginger. This is to be introduced up the rectum as high as possible, and the horse is to be then moved briskly about. An onion put up the fundament whole has long been a domestic remedy. The following is recommended by Blaine — *Spirits of vitriol either an ounce powdered opium, one drachm oil of turpentine three ounces warm etc a pint.* He also recommends the following more simple remedy as always at hand — *The expressed juice of two or three large onions comminuted, common oil, of each half a pint wax and pine.* White recommends a pint of brandy, or of gin with water, as an excellent carminative. Clark, who has expressly written on gripes, extols the virtues of a mixture thus made which, if it have the qualities he attributes to it, and which there is no reason to doubt, no agricultural, coach or post master should be without it. — *Pinenut berry, called also allspice, ground fine half a pound spirits of wine, and of water of each a pint and half* infuse these together and keep for use. Give a quarter of a pint ev'ry hour until full relief is obtained hand rubbing, wring or flogging the bowels with hot water at the time.

6478. *Inflammation of the intestines from wounds in the belly frequently occurs, and these injuries may happen in leaping over hedges or pale gates, or may be inflicted by the horns of a cow.* Sometimes the strong tendinous covering of the belly is ruptured, while the skin remains entire. The gut then protrudes and forces out the skin into a tumour. The first thing to be done is to put the gut back, taking care at the same time, wherever extensive inflammation follows to remove any dirt or other matter that may be sticking to it. For which purpose, should it be found necessary it may be washed with warm water but with nothing stronger. If the gut cannot be returned, from its being full of air and the opening in the belly be too small to put it back again, such opening may be carefully enlarged to the necessary size but if the animal can be thrown upon his back conveniently a great deal may be done that cannot otherwise be accomplished. After the gut is returned the skin only should be stitched up, and a cushion of several folds of old linen and tow being placed in the wound, it should be kept in its situation by means of a wide bandage rolled round the body and carefully secured. The animal should then be copiously bled, and have his bowels emptied by clysters. The only food he should be allowed is grass, or bran mashes, and that only in moderate quantity. When the distention of the intestines wholly prevents their return it would be prudent to puncture them with a very fine instrument, and thus to suffer the air to escape which, although subjecting the horse to the risk of inflammation, is better than the certainty of death by having the intestines protruded.

6479. *Worms of horses are of several kinds. First, bots in the stomach but which, as they mostly attach themselves to the hard inextensible part of that organ seldom do harm.* Clark fancifully supposes they do good, and devises means for furnishing them when not in existence. The bot is the larva of the *G. stercor.* a fly which deposits its eggs, it is supposed, on the grasses on which horses feed and probably on parts of the horse himself, from whence they pass into the stomach by the food or by being licked off. Certain it is they get there, are hatched, and there remain hanging to the coats of it by two tentacula, revolving the juices of the masticated food as nutriment. After a considerable time they make their way out by the anus drop on the ground, and are first transformed into chrysalids, and afterwards into parent flies. When bots fix themselves on the sensitive portion of the stomach they may do harm; but no medicine that we know of will destroy them. The liver or large round worm sometimes occasions mischief when it exists in great numbers, such as a staring coat, binding of the hide, irregular appetite, and clammy mouth. The best remedy is the *Spigelia marylandica* or Indian pink, in daily doses of half an ounce. The bots are not common in the horse now and then they exist, and are best combated by weekly doses of oil of turpentine, three ounces at a time, mixed by means of the yolk of an egg with half a pint of ale. The *Ascaris* or thread-worms are best removed by mercurial purgatives. The existence of worms may be known by the appearance of a yellow matter under the tail, and by the disposition the horse has to rub his fundament. Blaine recommends the following vermifuge — *Powdered arsenic eight grains; powder of the fleshy scraped; Fœtus turpentine, half an ounce* make into a ball, and give every morning. He also recommends salt to be given daily with the food; which agrees with our own experience as one of the best vermifuges known. It is a fact acknowledged by the residents along the sea-coast, that horses troubled with worms will often voluntarily drink largely of sea water, and thus cure themselves.

6480. *The diseases of the liver are acute inflammation or hepatitis, and chronic inflammation or jaundice.* *Hepatitis* is the acute inflammation of this organ, which like the lungs, stomach, and intestines, may spontaneously take on the affection. The symptoms are not unlike those which attend red colic, but with

less violence. If it be not, however, arrested, the termination will be equally fatal. About the third day the whites of the eyes turn yellow and the mouth also. Bleeding, blistering, and purgatives form the methods of cure as practiced in real cases.

**640. Chronic inflammation or yellow.** The liver of horses is less complex than that of many other animals, and is therefore not very liable to disease; indeed some authors affirm that the horse is never affected with jaundice, but that the yellowness of skin is a mere stomach affection; this is, however, erroneous and not only does the liver become hardened and thickened occasionally but the bile becomes diseased and is thrown out in that state by the blood over the body. If fever be present, bleed, but if the symptoms present be those of active inflammation, give each night ten grains of calomel, and every ten days wrick it off with a mild dose of purgals. It is, however, necessary to remark, that it is not every yellowness of the skin that betokens either an acute or chronic inflammation of the liver. It is the property of every serious inflammation of any of the important organs of the chest and belly to communicate a portion of the evil to the other organs immediately in conjunction with the liver; thus an affection of the stomach or intestines, of the inflammatory kind, very often occasions redness of the membranes of the nose, eyelids, &c. &c.

**641. Disease of the urinary organs.** Inflammation of the kidneys is an idiopathic affection, not one of frequent occurrence but as brought on by injuries, such as over-riding, heavy loads, or violent diarrhoea, it is not unfrequent where idiopathic, it may be the effect either of cold, heating food, or a translocation of some other inflammation, in which cases, it comes on suddenly and assumes the same febrile appearances that other intestinal inflammations produce but there is not often great apparent pain but a frequent inclination to stale the quantity made being so small as almost to amount to a stoppage of urine, which is less or more complete, as one or both kidneys are affected. What little urine is made is also at first very thick and then bloody. When the disease is the effect of external injury the urine is not so scanty but is more bloody; and this symptom precedes the other. There is usually much pain and stiffness about the loins and we learn from Blaine that a swelling and a paralytic effusion of the hind leg of the side of the affected kidney is a feature in the complaint. To distinguish this inflammation from that of the neck or body of the bladder with which it may be confounded, the same author recommends that the hand be passed up the rectum when if the affection belong to the kidneys, the bladder, whether full or empty, will not be hotter than usual but the contrary occurs when any part of the bladder is the seat of the disease.

**642. The treatment** must be active, and in most respects similar to what has been recommended for red colic, as regards emptying the bowels, and endeavoring to lessen the arterial action by bleeding but here we must carefully abstain from irritating the kidneys by diuretics internally or blisters externally. A newly striped sheepskin placed over the loins, or active fomentations of hot water are the only sources of counter-irritation that are proper; neither should diluting liquors be pressed on account of the distention they occasion, but no evil can arise from frequent warm clystering.

**643. Inflammation of the bladder.** When the body of the bladder becomes inflamed, there is frequent staling from the very first attack but when the neck of the bladder is the seat of the evil, the expelling out of a few drops will only take place when the bladder has become filled, which may be known by passing the hand up the rectum. The treatment will be alike in both cases, and is the same as recommended for the last affection. It must be evident, that warm, mild, and frequent clystering must here be peculiarly advisable.

**644. Strangury or suppression of urine, incontinence of urine, bloody urine.** Strangury may arise from an injury done to the kidneys, or to the bladder by strain, or by the absorption of irritating matters. In these cases, bleed if there be fever, and if not, merely give the horse absolute rest—mash him, give gruel, and warm his water for drink. *Bloody urine* should be treated in the same way—some horses have such a natural or acquired weakness of kidneys, as to stale blood with their urine on every cessation of exertion—the means frequently used for relief are such as aggravate the complaint, and indeed are often the occasion of it, which are diuretics. Strong diuretics injure horses more than strong phlebotomy, and benefit them less than any other of the popular means made use of. In retentions of urine, but particularly in the case of bloody urine they are absolutely improper.

**645. Diabetes profusus staling or stinging evil.** This disease is more frequently forced on the horse by long-continued diarrhoea, or from a similar effect brought on by kiln-dried oats, mow burnt hay and some green vegetables, thus acquired from constitutional indisposition. The horse first stales often and gradually he then becomes weak and faint, and sweats on any exertion. If it be at all constitutional his kidneys are bound from the beginning, and his urine will have a sweet taste but if his appetite were good, and his coat sleek, bright, and elastic when the urine was first observed to be immoderate, the evil arises from some fault in the feeding, clothing, exercise, or other management of the horse. Examine into these matters, particularly into the food, and treat the water. Enquire whether diuretics have been given, under an erroneous supposition of increasing the condition, and alter what may be amiss. If this do not remove the complaint, try the following after Blaine's directions.—*Lower of sulphur two drachms; one uret, four drachms—oil bark, one ounce; catechu, half an ounce—alum, half a drachm*—give as a daily drink in a pint of water.

**646. Stones and gravel.** Calculous concretions are not uncommon in the large intestines of horses, where they grow sometimes to an enormous size, lodged in one of the coils usually and where they occasion but little inconvenience, except a displacement occurs, when serious evils, as colic inflammation, or total stoppage, follow. In the bladder stones is very seldom found; and there is reason to believe, that though gravel is a common term in the farrier's list, that it seldom if ever occurs—injuries of the kidneys and bladder being usually mistaken for it.

#### SUBJECT 6 Diseases of the Skin.

**647. Mange is a contagious disease** not uncommon among low bred and badly kept horses, but which is seldom generated in those properly managed. When it is the effect of impoverished blood, a different course of feeding must be substituted, not heating, but cooling though generous; as, carrots, spiced corn, mash, mangel, stable molasses, &c. When it arises in full-fed horses, bleed freely, lower the feeding, substituting for corn mangel, carrots, or barn mashes. Give a tightly alterative (*Vol. Pharm. 633. No. 1. or 2.*) and dress with either of the mange dressings. (*Vol. Pharm. 636.*) After a cure has been effected, carefully clean all the apartments with soap and water.

**648. Stuffed with new and then degenerate into mange** but more generally it is brought on by a fulness of humors noted on by sudden transitions from cold to heat, or heat to cold; if it is likewise not untruly the consequence of over-feeding. If it shows a disposition to spread, and the skin become sore and scurfy treat as under mange; otherwise treat as directed under want of condition. (*645*)

**649. Warts** are of the nature of carbuncles in many instances, in others they are brought on by the pressure of the saddle which either suppurates and bursts, or become indolent and remain under the name of *siglets*. In the early state, bathe them with chamæmyris or vinegar. If they proceed to suppuration, restrain; and when they neither go back nor come forward, put on a pitch plaster and if this do not promote resolution, let the attack be dissipated out.

**650. Warts are common to old horses**, and had better be put up with, unless they be situated in some inconvenient or very conspicuous part. In this case, tie a thread tightly around the root, and the wart will drop off, or it may be cut off. Blaine recommends the following, when warts are too numerous to be so removed.—*Crusts cut numerous, two drachms; powdered camph, one ounce; lard, one ounce and a half*. Rubb them in a circle of the skin, where the internal matter between that and the fleshy part.

sicle is not in a state to allow of its pliancy and elasticity. The binding down of the hide thus closely sets on the hair, which it generates in a contrary direction to its naturally inclined position; and thus a starting coat usually produces hide binding. In considering the subject of condition (955), we have seen that it is not a disease of itself, but in every instance a symptom only.

#### SUBJECT 7. *Glanders and Farcy.*

952. *The glanders* is the approbrium medicorum for hitherto no attempts have succeeded in the cure of more than a few cases. By some peculiar anomaly in the constitution of the horse, although conclusive proofs are not wanting that this and farcy are modifications of one disease, and that each generates the other; yet the one is incurable, while the other is cured every day. When glanders has been cured, the time and labour necessary to accomplish the end has swallowed up the value of the horse, and has also in many supposed instances of cure, left the animal liable to future attacks which have occurred. The experiments on glanders, pursued at the veterinary college and by White of Exeter have thrown great light on the disease itself, its causes, connections, and consequences, but have done little more. From these we are led to conclude that glanders will produce farcy, and that farcy can produce glanders; that glanders is highly infectious, and that such infection may be received by the stomach, or by the skin when it is at all abraded or sore; and it is also probable, that it is received by the nose of horses being rubbed against each other. While a experiments go to prove that the air of a glandered stable is not infectious, but this matter is by no means certain and should not be depended on without a greater body of evidence.

953. *The marks of glanders* are a discharge of purulent matter from ulcers situated in one or both nostrils, more often from the left than the right. This discharge soon becomes glairy, thick, and white-egg-like. It afterwards shows bloody streaks, and is fetid. The glands of the jaw of the affected side, called the kernels, swell from an absorption of the virus or poison; and as they exist or do not exist, or as they adhere to the bone or are detached from it, so some prognostic is vainly attempted by farriers, with regard to the disease. For in some few cases glands are not at all affected, and in a great many they are not bound down by the affection to the jaw. As there are many diseases which excite an accretion of matter from the nose, and which is kept up a considerable time, so it is not always easy to detect glanders in its early stages. Strangles and violent colds keep up a discharge from the nostrils for weeks sometimes. In such cases a criterion may be drawn from the existence of ulceration within the nose, whenever the disease has become confirmed. These glanderous chancres are to be seen on opening the nostril a little way up the cavity sometimes immediately opposed to the opening of the nostril. But a solitary chancre should not determine the judgment. The health often continues good, and sometimes the condition also, until hectic takes place from absorption, and the lungs participate, when death soon closes the scene.

954. *The treatment of glanders* it has already been stated, is so uncertain that it is hardly worth the attempt; however, where the extreme value of the horse or the love of experiment leads to it, it may be regarded as fixed by experience, that nothing but a long course of internal remedies, drawn from the mineral acids, can effect it. These have all been tried in their endless variety. White recommends the mildest preparations of mercury as *sedative mineral* under the conviction that the more sordid preparations disturb the powers of the constitution so much as to destroy as effectually as the disease. At the veterinary college of copper (blue vitriol) has been long in use. Others have used the sulphates of iron and zinc. Clark recommends the daily administration of a drink or ball, composed of the following ingredients:—*Sulphate of zinc 15 grains powdered caltharides 7 grains; powdered allspice 15 grains*; of the utility of which he gives one or two extraordinary proofs, and Mr Sewell still attaches much importance to its use, in such daily doses as the stomach will bear. Blaine appears but little sanguine as to any medical treatment, but recommends a union of the mineral acids in the same proportions, and with the same cautions, as are detailed under farcy (949).

955. *The farcy is a disease more easily cured than the glanders* of which our daily experience convinces us, farcy or farcin, attacks under distinct forms, one of which affects the lymphatics of the skin and is called the *bad or broken farcy*; the other is principally confined to the hind legs, which it affects by large indurations, attended with heat and tenderness. A mere dropsical accumulation of water in the legs sometimes receives the name of *water-farcy*, but this has no connection whatever with the true disease in question. Farcy is very contagious, and is gained from either the matter of farcy or from that of glanders.

956. *Treatment of farcy.* The distended lymphatics or buds may often be traced to one sore, which was the originally inoculated part; and in these cases the destruction of this sore, and that of all the scirred buds, will frequently at once cure the disease, which is here purely local. But when the disease has proceeded farther the virus must be destroyed through the medium of the stomach, although even in these cases the cure is rendered more speedily and certain by destroying all the diseased buds by caustic or by cautery. Perhaps no mode is better than the dividing them with a sharp firing-iron or if deeper seated, by opening each with a lancet, and touching the inner surface with *lapis infernalis*. The various mineral acids may any of them be tried as internal remedies with confidence, never losing sight of the necessity of watching their effects narrowly, and as soon as any disengagement of the health appears, to desert from their use. *Oxymercurate of quicksilver* (corrosive sublimate) may be given in daily doses of fifteen grains, *acids of arsenic* may also be given in similar doses. The *subcarbonate of copper* (verdigris) may also be tried, often with great advantage in doses of a drachm daily. Blaine joins these preparations, and strongly recommends the following:—*Oxymercurate of quicksilver oxide of arsenic subcarbonate of copper of each eight grains; sulphate of copper one scruple* make into a ball and give every morning, carefully watching the effects and if it be found to occasion distress, divide and give half night and morning. The same author professes to have received great benefit from the use of the following:—*The expressed juice of elvers or goose-grass a strong decoction of leopards and of assafras, of each six ounces*, to be given after the ball. It remains to say, that whatever treatment is pursued either with respect to farcy or glanders will be rendered doubly efficacious if green meat be procured, and the horse be fed wholly on it; provided the bowels will bear such food but if the medicine gripe, by being joined with green food, add to the diet bean-meal. When green meat cannot be procured, carrots usually can, and when they cannot, still potatoes may be boiled, or the corn may be sparged or malted. As a proof of the beneficial effects of green meat a horse, so bad with farcy as to be entirely despairing of, was drawn into a field of tares, and nothing more was done to him, nor further notice taken of him, although so ill as to be unable to rise from the ground when drawn there. By the time he had eaten all the tares within his reach, he was enabled to struggle to more, finally he rose to extend his search and perfectly recovered.

#### SUBJECT 8. *Diseases of the Extremities.*

957. *Shoulder strains* are very rare, most of the lamenesses attributed to the shoulder belong to other parts, and particularly to the elbow. Out of one hundred and twenty cases of lameness in the fore and middle Blaine found that three only arose from ligamentary or muscular extension of the shoulder. When a shoulder strain does happen, it is commonly the consequence of some slip, by which the arm is forced violently outwards. It is less to be wondered at than at first seems probable, that horses subjected to lameness for shoulder strains, when we reflect that a contracted neck occasions lameness, and a disposition to favour the limb by pointing it forward, which thus wastes the muscles of the shoulder. Seeing one shoulder smaller than the other the evil is supposed to be there, and it is pegged, bled, and fired,

or the horse is swum far to his nostrils, and the laceration of the foot's construction by the confinement. In cold shivering chills, the leg is dragged along the ground while in motion; at rest it is flung forward, but resting on the point of the toe. When the lameness is in the foot, the horse points his foot forward also, but he does so with the whole limb arched, and the foot flat. These differences are highly necessary to attend to, as well as the peculiar difficulty which is always apparent in moving down hill, which he does with reluctance, and by swinging his leg round to avoid facing it. This lameness may be further brought to the test by lifting up the fore leg considerably, which, if the evil be in the shoulder will give great pain. The soundness between the fore legs are likewise hummed and tender in these cases.

**6598.** The treatment consists, when it is recent, in bleeding in the plain vein, swelling in the chest, and fomenting with hot water two or three times a day. When the heat and tenderness have subsided, first bathe daily with the astringent wash for strains (*See Pharm.* 6535, No. 1.) for a week; and afterwards, if necessary proceed to blister in the usual manner.

**6599.** Strains in the active lines. (*See* 1.) This important joint is sometimes strained, or its ligaments and muscles unnaturally extended, from a greater force being applied to them than their structure is able to bear, or their powers to resist. A laceration takes place of some of their fibrille, or in lesser ruptures their elasticity is injured by being put on the stretch beyond their power of overcoming again. In all such cases, the parts relax, and inflammation follows by which heat, tenderness, and swelling ensue.

**6600.** Treatment. The first indication is the same in this as in all ligamentary strains, which is to moderate the inflammation by fomentations, &c. &c. and when that has subsided, to endeavour by astringents and blisters to restore the tone of the parts after which if any swelling remains, from the extravasated blood becoming organized, to promote its absorption by mercurial frictions, and blistering. This applies to all strains and will direct the treatment therefore of that of strain in the articulation of the thigh with the body also.

**6601.** Strain in the elbow, is treated in the same manner.

**6602.** Strain or clasp in the back struts. This is generally an injury done to the sheaths of the tendons, or of the ligaments which bind them down. In very aggravated cases, it sometimes occurs that even the tendons themselves are extended beyond their capacity. The heat, swelling, and tenderness are first to be combated by fomentations, and if these be extreme, bleed also, and give a dose of physic. Next proceed to poultice with saturating applications, until the heat and swelling are reduced, then use tonics, astringent wash (*See Pharm.* 6535, No. 1. or 2.) bandages and exercise very carefully. If swelling remains after heat, pain, and lameness are past, or when lameness only remains, after all heat is gone, proceed to blister mildly twice. In all cases of ligamentary extension when the heat has subsided, the part may be considered as in a state of stony; and bandages judiciously applied are then proper particularly during the day.

**6603.** Rupture of the tendons and ligaments of the leg. It is very seldom that the tendons themselves are ruptured, but the suspensory ligaments are more so, and the evil is called breaking down. It is usually very sudden, and the fetlock is brought almost to the ground. A perfect cure is seldom obtained but the inflammation should be moderated by the means already described, and the heels should be raised. A loose stocking or firm bandage, when the inflammation has subsided, is necessary and firing is often prudent as a permanent bandage.

**6604.** Rupture of the ligaments of the fetlock and coffin joints often occur, and may always be distinguished by the heat, tenderness, and swelling. Treat as already described. In all strains of the leg, attended with inflammation, a goulard poultice is a convenient and useful application. The goulard water should be mixed with bran and a worsted stocking being drawn over the foot, and up the leg, it is first laid around the spot, the poultice is then put in, and the stocking fastened around the leg above the injury (*6536*).

**6605.** Mediators and exudations are scarcely easily eruptions affecting the back of the knee, and ply of the hock; common only in coarse, low-bred, and in cart horses. Wash with soft soap every day after which anoint with an unguent formed of equal parts of mercurial ointment, tar and calamine luteate.

**6606.** Broken knees. The usual cause of broken knees are referrible to wounds in general and the treatment of them in nowise differs therefrom, with this caution that here it is more immediately necessary, both for appearance and safety that if any flap of skin hang apart, to cut it off or the wound will heal with repellent edges. But when the joint of the knee is broken into by the violence of the injury it becomes of a very different nature, and is known first by the extreme lameness and swelling that occur; and next, by the escape of a slippery mucus not unlike the white of an egg. If this continue to escape, violent inflammation follows, and either the horse or the joint are lost by it. Farriers are apt to attempt to stop the flow of the joint off as it is called by oil of vitriol, or other escharotics, which treatment is usually followed by the most disastrous consequences. It is however necessary to stop the immediate flow by other means, the best of which is by a fine budding-iron heated. Should the laceration be considerable, this cannot be done but the treatment must then consist of saturating poultices bleeding, low diet, and the other antifebrile remedies, until the swelling has subsided, when apply the astringent paste recommended by Clark, made of pipe-clay and alum, every day; but by no means introduce any escharotics.

**6607.** Splints and bone spavins. The former are usually situated on the inner side of the canon or shank bone; and as they are situated, so they are more or less injurious. When buried, as it were, within the tendons or back sinews, they are very apt to lame the horse seriously but when situated on the plain bone, unless they be very large, they seldom do much injury. If a splint be early attended to, it is seldom difficult to remove. Blaine recommends the swelling to be rubbed night and morning for five or six days, with a decoction of mercurial ointment, rubbing it well in, after which to apply a blister and at the end of a fortnight or three weeks to apply another. In very bad cases, he recommends firing in the bone sinews.

**6608.** Bone spavin is an exostosis of the hock bones, the treatment of which in nowise differs from that of splint except that as a spavin in general is more injurious than a splint, so it is more necessary to commence the treatment early and to continue it energetically. From the greater complexity of structure in the hock, spavin is not so easily removed as splint, and more usually requires the application of firing.

**6609.** Ring bone is of the same nature, being an exostosis or bony circle formed around the coronet, the treatment of which is the same with that of splint and spavin.

**6610.** Blood spavin, leg spavin, and thoroughspins, are all of them originally of the nature of windgalls, and are nothing more than enlargements of the bursal capsules described in the anatomy as surrounding tendons, ligaments, and bursae, to furnish them with a lubricating medium. By over-excitation or hard work these bursal bags become extended, and their contents increased and distended into puffly swellings in the hock, called, when on the ply, leg spavin. The pressure of this sometimes occasions a varicose state of the superficial vein, which passes directly over it on the inner side of the hock, and which enlargement then receives the name of blood spavin. When the bursal enlargement extends through the hock, it is called thoroughspin. When it is situated below in the bursae of the flexor tendons, near the fetlock joint, it receives the name of callosity.

**6611.** The treatment of all these cases must be similar in principle, and consists in lessening the distended sac; not as was formerly practised, to the destruction of the horse often, by letting out the contents of these windgalls; but by strengthening the sides of the tumours by stimulants or by pressure. The more active stimulants are the liquid blister (*See Pharm.* 6536), milder ones are found in the astringent wash. (*See Pharm.* 6536 No. 1.) Bandages must greatly, when well applied to the part, and in desperate cases firing has been resorted to, which is nothing more than a more violent stimulus, and a more permanent bandage.

6512. *Capsitis* is a tumid enlargement of the point of the heel, and is to be treated by friction, astringents, and bandages.

6513. *Cors* is an inflammation of the ligaments at the back of the heel, and is usually removed by astringents. (*Vet. Pharm.* 6555.) When it does not give way to these, the swelling liquid blister may be applied. (*Vet. Pharm.* 6553.)

6514. *Cracks and greases* may be considered as modifications of one and the same affection, and are commonly brought on by some neglect in all horses; but when they occur in any but the thick-heeled low bred animals, they are invariably so. Over-feeding or under-feeding, but much more frequently the former will bring it on. A very frequent cause of it is the practice of washing the legs of horses, and suffering them to dry of themselves. In every case, without exception, washing the legs should be avoided unless they be rubbed perfectly dry afterwards. When horses have long hair about their heels, and are washed and thus left wet, the evil must be doubled as the evaporation going on, cools and chills the heels, and thus produces a species of chilblain, and we well know how difficult these are to heal when broken. Cracks in the heels very often occur in horses run too suddenly into full keep from previous stow or grass, or from these to a hot stable, which, by the heat and moisture of the litter occasions a determination of blood and humours to the legs, and they break out into cracks or scabs, from which issue a bloody ichor or a more thick matter. Between the scabs the hair stars and gets painful, and the horse finds difficulty and pain in moving.

6515. The treatment must depend on the state in which the animal is at present. If there be reason to suspect the horse to be full and foul, bleed, lower his food, soil him in the stable or wash and give a solid dose of physic. But when some mismanagement is the sole cause, remove that, and if the case be a severe one by means of an old stocking drawn over the foot, bury the whole heel in a poultice made of scraped carrots or turneps which will subside the irritation and bring the parts into a state to bear the application of the astringents. (*Vet. Pharm.* 6571 No. 2.) or if more convenient, of the extractum of the astringents. (*Vet. Pharm.* 6556. No. 1 or 2.) Moderate exercise should be continued, and the heels carefully cleaned from dirt by soft soap and water so each return thereto after which always apply the astringent.

6516. Grease is nothing more than an aggravated state of the same affection, and is more common to the hind than to the fore legs. Coarse fleshy legged horses are peculiarly prone to the affection, from the great accumulation of sediment in their legs, and from the difficulty that the capillaries find in carrying the increased quantity of lymph upwards, and these long stable confinement should be avoided when that is impossible, it should be counteracted by exercise frequently and judiciously administered. Many cart horses never go out but to work they often work three days incessantly or nearly so; and they perhaps rest two days entirely. Can it be wondered at that the change occasions swelling, acting on the weakness and exhaustion of previous fatigue? and could not this be avoided by turning out for an hour or waiting for half an hour night and morning? Stable soiling should be used; bleeding and physicking also in very bad cases; and when the inflammation and irritation or soreness are great, the poultices recommended for cracks should be applied until these circumstances are removed afterwards commence the use of some of the astringents recommended. (*Vet. Pharm.* 6555.) White has stated two remarkable cases of grease cured by the application of corrosive sublimate, in the form of a wash as of two drachms of sublimate to ten ounces of water, increasing it to three drachms, if the pain occasioned by the first be not too considerable. Blaine says that the clivers or scum-grease has been known to be of great service in bad cases of grease half a pint of the expressed juice to be given daily as a drink; and a poultice of the herb *h.* be applied to the heels. In some cases of long standing when the running has ceased, a thickened state of the limb remains, which is best removed by firing, and which likewise is a preventive to a return.

#### SUMMARY 9 Diseases of the Feet.

6517. *Founder of the feet* is of two kinds acute and chronic. *Acute founder* is a disease that, until lately, was less understood than almost any other. After a very severe day's work, or when very much heated, if a horse get a sudden chill by standing in snow or cold water it is not uncommon for him to be seized with universal stiffness and every symptom of great fever. Such a horse is said to be *very rose-drawn*. By degrees, however, it is observed that the animal has an extreme disinclination to remain on his feet; from whence it will appear that the whole of them are affected. When the horse draws his hind feet under him, his fore only are affected and when he draws his fore feet under him, the hinder feet are the seat of the complaint; but which is seldom the case. On feeling the feet they will be found intensely hot and the pulsations arteries will beat with great violence. After a few days, unless the disease abate, a separation of the hoofs from the coronet takes place and at last they fall entirely off.

6518. *The treatment*. As the commencement of the disease bleed largely as well by the neck as from the toe of each affected foot, by paring until the blood flows freely. After which immerse each foot in a goulard poultice (6538) give the fever powder or drink (*Vet. Pharm.* 6576 and 6579.) litter up to the belly and if amendment do not take place, renew the bleedings, and blister round the pasterns.

6519. *Chronic founder contraction or fever in the feet*. The artificial life that horses lead subjects them to many diseases one of the principal of which is that of contracted feet. Blaine considers a neglect of sufficient paring of hoof the application of artificial heat from hot stables and hotter litter, the deprivation of natural moisture, constitutional liability and the existence of thrushes, as among the principal causes of this evil. It is more common to blood horses than to others and he observes, that dark chestnuts are of all others most prone to it. The appearance of a contracted foot, as contracted with a healthy one, we have already displayed. (6499.) It is there shown that the contracted hoof becomes longer higher and narrower the heels (*fig.* 637 c a) particularly are drawn in, and seem to sew the frog between them which becomes wasted and thrushy from this pressure. The hinder hoofs are seldom affected.

6520. *The treatment of contraction in the feet*. It is better to prevent, than to be under the necessity of attempting to cure, the evil. Prevention may be practised by avoiding the exciting causes. As soon as at all suspected to be likely to occur keep the hoofs pared low; never suffer the horse to stand on litter nor allow the stable to be too hot feed moderately and never allow the horse to go without daily exercise whatever increases the general fulness of habit, flies to the feet. Above all, keep the feet moist by means of wet cloths tied loosely around the coronet, falling over the whole hoof, but not extending beyond the edges. Then moisture repeatedly and stop the feet (6567) every night. When contraction has already taken place, many plans have been recommended as followed above by Coleman, Clark, and others; but it is not found that mechanical expansion in this way produces permanent benefit. The most effectual mode is to obviate all previous causes of contraction and then to this the hoofs around the heels from each quarter so thin as to be able to produce an impression by means of the thumb in fact, to remove so much of the horn as is consistent with safety from the coronet downwards. It is also prudent to put in a screw or two from above downwards, drawn a quarter of an inch deep on each side towards the front of the hoof; but whether this be done or not, the front of the hoof should be rasped thin about an inch in width; by which means a hinge is formed, which operates most advantageously in opening the heels. After this is done, the shoe should be put on, and the horse should be turned out to grass, where he should remain three months, by which time the new formed heels will have reached the ground, and will bear a shoe. This process is fully described by Blaine in his *Farriery Questions*, where a plate completely illustrates the operation, and to which we would commend the reader.

6521. *The powdered foot* is a very common consequence of acute founder in which the elasticity of the laminae becoming destroyed, the support of the coffin bone is removed, and it rests wholly on the sole,

which it gradually sinks from a concave to a convex surface, drawing with it the front of the hoof inward. In weak, heavy feet, this evil comes on sometimes without founder; the treatment can be only palliative, a wide-valued shoe exactly fitted to the foot, without at all pressing on it, prevents the inflammation consequent to the disease. A shoe exactly the contrary to this has been tried in some cases with benefit, the form of which has been one with a web so narrow as only to cover the crown, but so thick as to remove the foot from accidental pressure. In other cases, no shoe answers so well as a strong bar shoe. (650.)

652. Corns are most troublesome diseases, to which horses are very liable, and which injure and ruin thousands. They are wholly accidental, no horse having any peculiar tendency to them, but being always brought on them by some improper pressure, usually of the shoe, or from something getting in between the shoe and the horny hoof. A shoe too long worn is a very common cause, and a still more frequent one is the rubbing the heels of the shoe, neither is it necessary to the production of corns, that the shoe itself should press on the sole, but they are equally produced when the outer horn of the heels or of the bars is the immediate offending part, rendered so by too luxuriant growth, by unequal wear, or by secondary pressure from the shoe, or by gravel working in. (See 636.) It is the fleshy sole itself that is bruised, from which a speck of extravasated blood follows, and if not immediately relieved, it gathers, or the part becomes habitually defective, and instead of forming healthy horn it always afterwards forms a spongy substance of extreme sensibility and thus is always liable to produce pain and lameness when exposed to pressure.

653. The treatment of corns is seldom difficult or unsuccessful at their first appearance, but afterwards it can be only palliative. Blaine directs that by means of a fine drawing-knife every portion of diseased horn should be pared away and the extravasation underneath likewise. Having done this, he advises to introduce some *baler of anatomy* into the opening, to place over this some tow which should be kept in its place by means of a quilt. If any constriction of the heels (See 636. a.) be present, it will materially assist the cure to lower them, and to this the hoof a little around the quarters, and afterwards to put on a shoe without heels exposed to the corn or a shoe chambered opposite the weak part or a bar shoe may be applied, so framed as completely to leave the heel untouched. Introduce the butter of antimony once or twice more, with the interval of two days between, and then turn the horse out to grass. In about six weeks time the foot will be sound, if it be guarded by means of wood passed under the shoe, to prevent it from being again injured. For although they are never wholly eradicated they may be rendered but little troublesome. The diseased part must be carefully pared out at each shoeing, and such a shoe put on as will completely free the heel from pressure.

654. *Humors thrush is always a dangerous disease*, and few errors in horse management are more glaring than the common one of supposing they are necessary to carry off humors. If less food, more exercise, and dry stables, were substituted to correct the fulness, instead of thrushes, which invariably contract the foot whenever they continue any length of time, many valuable horses would be saved to the community. To the cure, begin by clearing out all the fissures of the frog (See 636. a.) from loose ragged horn and then introduce to the bottom of the fissures, by means of a thin piece of wood, some of the *thrust paste* (See Pharm. 654.), smeared on tow which will enable it to be held within the crack, especially if it be guarded by means of wood passed under the shoe, to prevent the dressing daily carrying out to grass may be practiced to great advantage for thrushes by this mode of dressing, but without it the disease is sometimes aggravated.

655. *Bandicorns are frequent in the hoofs*, commonly of those before, and usually towards the inner but new and then towards the outer quarter also, from above downwards from the crack, a little oozing of blood or moisture is seen; and the sensible parts underneath getting between the edges of horn become pressed on and lose the form. Turn the figure crossways, so as to destroy the connection between the divided and the undivided parts of the hoof. With melted pitch close up the origin if the oozing be moderate and bandage tightly. Watch the foot, and if inflammation succeed this plan, remove the dressing.

656. *Pricks or punctures in the feet* are often very serious evils, either when received by nails in shoeing, or by not picking out the root, or by the danger arising from the inflammation, which is always produced by any injury done to the sensible and vascular parts within the foot. This inflammation seldom proceeds to suppuration; and the matter is apt to make its way upwards, unless it find a ready vent below. When it does not break out at the coronet, it will often penetrate under the sole, and finally disease the bones, ligaments, or cartilages, and produce quittor. It is very seldom that a horse is pricked in shoeing, but that the smith is aware of it by the peculiarity of the feel on the hammer and by the smothering of the animal. At such times were he to immediately withdraw the nail a little, enlarge the opening, and introduce some spirit within the puncture, nothing would occur but on the contrary he sends the horse home to avoid trouble, who, the next or following day is found lame, and with his foot hot. If the nail be only driven too near the sensible lamina, it will only require to be removed to free the horse from his evil, but if it have been driven through and have wounded them, it is suppuration ensues, and so examining the foot by the pincers when the shoe is removed, he will finish at the pressure on the diseased part. It is probable, on the removal of the shoe that matter will at once flow out at the immediate nail hole. If not, the drawing-knife will soon detect the injury. If the heat be great, and instead of matter bloody dark ichor flows out, wrap the foot up in a poultice but if healthy matter flows out, this will not be necessary sometimes it is requisite to detach all the horn that is underlain by the matter; but when the injury has not proceeded to this extent, apply over the part a pledget of tow steeped in fish's balsam; tack on the shoe lightly and retain the dressing by means of *spikes* which are thin pieces of wood (the witty which binds birch brooms is convenient for the purpose) passed under the shoe; repeat the dressing daily and avoid moisture, which would encourage quittor. A nail picked up on the road, and which passes through the sole, below or through the frog, is to be treated in the same manner, and also when the matter breaks out at the coronet; but when a nail is picked up, and penetrates the coffin joint, which is known by the synovia or joint oil appearing, such opening should be immediately stopped by purging towards the wounded joint, and then applying a hooped banding iron, not to the capsular ligament itself but to the skin immediately near it; if this be inconvenient, put a pledget dipped in a little butter of antimony just within the opening, but do not press it into the cavity of the joint. If this be insufficient to stop the flow, but more particularly if the original wound penetrated to the bone, it is probable that the bone itself will become, in some measure, diseased, which is known by the rough grating felt at the points of the probe when pressed. In this case, enlarge the opening so as to be able to scrape the diseased bone away. *Strikes of the sole*, from whatever cause, will all fall under some of these points of view according as the case may be.

657. *Quittor and cancer are the consequences of their injuries* when neglected, or originally extensive. In these cases either the bones, ligaments, or cartilages, or all, become diseased and a cure can only be obtained by removing the diseased parts by the knife or by caustic.

658. *Trenches, or wounds in the coronet* are not uncommon from one foot being placed on the other; or the binder that may strike it, &c. First wipe away the dirt, and remove any loose edges that cannot unite; avoid washing, unless stones and dirt are suspected to be within, and bind up, having first placed over the wound a pledget of lint or tow moistened with balsamic tincture, or tincture of myrrh, or of alone, &c. *Over-reaching, or over-stepping* is often an injury done to the fetlock joint below, by the hinder foot, or to the hock joint higher up. Sometimes it is simply a violent bruise, at others the laceration is extensive, in which cases treat as a wound; and when no laceration has taken place treat as a bruise or strain.

659. *Cutting is a defect* to which some horses are liable from their form, as when they turn their bow

cut, or have bent legs. Others cut only when they are lean, which brings their legs nearer together. Weak horses cut because they cross their legs when fatigued, and young unfurnished horses cut at youthful periods, and grow out of it afterwards. The part in which a foot interferes with the opposed limb is very different. When it strikes the shank high up it is called *spandy cut*, and is best remedied by wearing knee-boots or rollers. When it is at the fetlock the cutting is at the side or rather backward, according to circumstances. Some horses cut by the edge of the shoe, others by the hoof at the quarters; and some by the point of the hoofs. It is to be remarked, that it is better to put up with the evil of cutting, than to do so as is too frequently done, which is, to pare away the hoof until it excites contraction. The shoe may be feather edged, or it may be set a little within the cutting quarter but by no means alter the size or the form of the hoofs themselves, and particularly avoid taking liberties of this kind with the fore feet. Boots, or rollers, are but little trouble to put on, and when not buckled too tight never injure whereas, to allow a horse to continue to cut produces a callos, and often throws the animal down.

#### SECT. VI. *Veterinary Operations.*

6330. *The general practices to be here enumerated are chiefly the treatment of wounds, the application of fomentations, setons, blisters, clysters, and physicking; and the operations of castrating, nicking, bleeding, &c.*

##### SUBJECT 1. *Treatment of Wounds.*

6331. *A wound must be treated, in some measure, according to the part of the horse's body in which it happens; but there are some principles to be observed alike in all horse surgery.* There are likewise a few which, as they differ from the principles of human surgery, should be first noticed, and which should guide the practice of those who might be misled by analogy. The wounds of horses, however carefully brought together and confined in their situation as well as shut out from the stimulus of the external air are seldom disposed to unite at once, or as it is called in surgical language, by the *first intention*. It is always, therefore, necessary to expect the suppurative process but as the adhesive inflammation does now and then occur, we should never wash a mere laceration with water or other liquids if no foreign matter as dirt, &c. be suspected to be lodged within it still less should we stuff it with candle tow or tents of any kind. On the contrary, it should be carefully and smoothly brought together and simply bound up in its own blood, and if it do not wholly unite at once, and by the *second intention* as perhaps some portion of it may; and if it all events its future progress will be more natural and the disfigurement less than when stuffed with tents, tow &c. or irritated with heating oils or spirits. When an extensively lacerated wound takes place it is common, and it is often necessary to insert sutures, or stitches, into the lips of the wound and here we have to notice another considerable variation from the principles of human inflammation, which is that these stitches in the horse ox, and dog soon become loose, seldom remaining longer than the third or fourth day at farthest. It is therefore the more necessary to be careful, that by periodical set, and the appropriation of good bandages we secure the wound from distortion. In this we may be assisted by strips of sticking plaster made with diachylon and pitch but these strips should be guarded from touching the wound itself by means of lint or tow first put over it. When, in addition to laceration in a wound, there is a destruction of substance, then the caution of washing will not apply, as it will be necessary to bathe with some warming spirit, as *sucrose of mercury*, *infusions of aloes* or *piperis* &c. to assist in restoring the life of the part, and in preventing mortification. Bleeding must be stopped by pressure and astringents as powdered alum when it is very considerable, the vessel from whence the blood comes must be taken up. When great inflammation follows wounds or bruises, counteract it by bleeding a cooling temperature, opening medicines and continual fomentations to the part itself.

##### SUBJECT 2. *Balls and Drinks.*

6332. *Mode of giving a ball.* Back the horse in his stall and being elevated on a stool (not a bucket turned upside down) gently draw the tongue a little out of the mouth, so as to prevent its rising to resist the passage of the hand; the tongue should however not be laid hold of above but it should be held firmly by the fingers of the left hand against the jaw. The ball previously oiled being taken into the right hand which should be squeezed into as narrow a shape as possible, must be passed up close to the roof of the mouth and the ball placed on the root of the tongue, when both hands being with drawn it will readily pass down. This mode is much preferable when a person is at all handy to using a balling iron. At Long's, veterinary surgeon's instrument maker is sold a clever machine for this purpose.

6333. *Mode of giving a drink.* Exactly the same process is pursued, except that a horn holding the liquid matter is forced up the mouth; the passage being raised beyond the level of the liquid is poured out from the larger end of the horn, and when the tongue is loosened it is swallowed. Clark, however ingeniously proposes to substitute the smaller end of the horn the larger being closed, by which, he says, the horn can be forced up the mouth between the teeth, and poured farther back so as to ensure its not returning.

##### SUBJECT 3. *Fomentations and Poultices.*

6334. *Fomentations* are very commonly recommended of various herbs as rue, chamomile, St John's wort, wormwood, bay leaves, &c. but the principal virtue is to be found in warmth and moisture, which assist the vessels, but this warmth ought not to be too considerable, except when the inflammation is within, as in inflamed bowels. Here we resort to stimulate the skin, and cannot foment too hot but when we do it at once to an inflamed part it ought not to be more than of blood heat, and it should be continued long, and when removed the part should be dried or covered or cold may be taken, and the inflammation increased instead of diminished. *Anodyne fomentations* are made of poppy heads, and of tobacco, and are frequently of great use.

6335. *The method of applying fomentations* is conveniently done by means of two large woollen cloths wrung out of the heated liquor as one is cooling the other should be ready to be applied.

6336. *Poultices* not in the same way as fomentations in allaying irritation and inflammation; but are in some respects more convenient, because they act continually. It is an error to suppose that poultices, to be beneficial, should be very hot however hot they may be applied, they soon become of the temperature of the surrounding parts. When poultices are applied to the extremities, a stocking as has been before stated, is a convenient method of application. When it is drawn over the leg and bound around the lower part of the hoof, or of the pastern, or otherwise, the matter of the poultice may be put within, and it may be then kept in its situation, if high up on the extremity by means of tape fastened to each part of it, and passed over the withers or back to the other side and again fastened to the stocking. In this way also, loose bandages may be retained from slipping down. Cold poultices are often useful in the inflammations arising from strains, &c. In these cases bran and goulard water form a convenient medium; but when the poultice is necessarily hot, a little flaxseed meal added to the bran will render it adhesive, and give it cohesiveness. It is a very necessary caution in this, as in every instance where bandages are wanted around the extremities, to have them broad and only so tight as to secure the matters contained, as in a poultice, or as in common bandaging.

#### SUMMARY 4. *Setons and Rowsels*

6527. *Setons* are often useful in keeping up a drain to draw what are termed humours from parts; or by their irritation on one part, they lessen the inflammation in another part not very remote, as when applied in the cheek for ophthalmia or inflamed eyes. They also in the same way lessen and soothe by exciting absorption. Another useful action they have is to make a dependent or convenient orifice for the escape of lodged matter. Thus a seton passed from the upper part of the opening of pole evil, through the upper part of the integuments of the neck, as low as the sinuses run, will often effect a cure without further application. The same with cutaneous warts, which sometimes run under the shoulder blade, and appear at the arm point. A which causes a blunt seton needle, of sufficient length to be passed down to that point, and to be then cut out upon, will form the only efficient mode of treatment. *Setons* may be passed in domestic surgery with a common packing needle and a chain of thread or piece of tape. But in professional surgery they are made by a proper needle armed with tape or lamp cotton, or chains of thread or silk encased over with digestive ointment. When the seton needle is removed, the ends of the tape should be joined together or otherwise knotted, to prevent them from coming out.

6528. *Rowsels* in their intention act as setons, and as irritating a larger surface, so when a general drain is required they act better. as in gonorrhoea, &c. but when their action is confined to a part only setons are more convenient. Any person may apply a rowel by making an incision in the loose skin about an inch, separating with the finger its adhesions around, and then inserting in the opening a piece of round leather with a hole in the middle smeared with a blistering ointment. Then plug the opening with tow and in three days, when the suppuration has begun, remove it. The rowel leather is afterwards to be daily moved and cleaned.

#### SUMMARY 5. *Blistering and Firing*

6529. *Blistering* answers the same purpose as setons and is practised by first cutting or shaving the hair from the part, where the blistering ointment (*See Pharm.* 6521) should be well rubbed in for ten minutes, or a series of it the extent of the rubbing may be measured over the part. The head of the horse should now be tied up to prevent his gnawing or licking. If a neck cradle be at hand, it may also for safety be put on in which case the head may be let down the third day.

6530. A neck cradle for blistered horses is very convenient for other occasions also, when the mouth is to be kept from licking or biting other parts or to keep other parts from being rubbed against the head. It is of very simple construction, and may be made by a dozen pieces of wood of about an inch and half in diameter as old broom handles, &c. These bored at each end admit a rope to be passed through and as each is passed on, a knot may be tied to the upper part of the pieces of the cradle, two inches apart and those which form the lower part, four inches by which means the neck will be fitted by the cradle when it is put on and the horse will be prevented from bending his head to lick or gnaw parts to be protected. When the lower parts of the legs, particularly of the hinders require blistering, it is necessary to bear in mind that in gross full horses, particularly in autumn, grease is very apt to follow blistering, and almost certainly if the back of the heels below the fetlock be blistered. First, therefore, smear this part over with lard or ointment, and afterwards avoid touching it with the ointment. After blistering in summer the horse is often turned out before the blistered parts are quite sound in this case guard them from sun by some kind of covering, or they may become fly blown and likewise the fourth or fifth day rub into the blistered part some oil or lard to prevent the skin from cracking.

6531. *Drawing or leeching blisters* (*See Pharm.* 6533) are only more gentle stimulants, which are daily applied to produce the same effects on a diseased part without removing the hair. Of course less activity is expected yet as the action is repeated, they are often more beneficial even than blistering itself as in old strains and stiffnesses.

6532. *Firing* as requiring the assistance of an experienced practitioner we shall not describe. It will be only prudent to point out that it is a more active mode of blistering and that it acts very powerfully as a stimulant, not only while its effects last as blisters do, but also after its escharotic effect is over by its pressure, and in that way it is that it operates so favourably in bony exostoses, as splints and spavins and in this way it is so useful in old ligamentary weaknesses because by lessening the distensibility of the skin it becomes a continual bandage to the part.

#### SUMMARY 6. *Clystering and Physicking*

6533. *Clystering* should always be preceded by *back-scrubbing* which consists in using one hand and arm, and passing them up the fundament, and by that means to remove all the dung balls that can be reached. The large pewter syringe for clystering is neither a useful nor safe machine. A much better consists in a turned box pipe, to which may be attached a large pig or ox bladder, by which four or five quarts of liquid can be administered at one time. (*See Pharm.* 6537) The pipe should be previously oiled, by which means it passes more easily. The liquor should then be steadily pressed up and when the pipe is removed, the tail should be held down over the fundament a little to prevent the return of the clyster. In some cases of a spasmodic nature, as gripes and locked jaw great force is made by the bowels to return the clyster and nothing but continued pressure over the fundament can enable it to be retained. *Clysters* act only as relaxing the bowels, but they may be used as means of nutriment when it cannot be taken by the mouth; as in locked jaw wounds of the mouth, throat, &c. &c. In locked jaw it was observed by Cullen, that he kept a horse alive many days by clysters alone and by clysters also many medicines may be given more conveniently than by the mouth.

6534. *Physicking of horses.* It is equally an error to refrain altogether from giving horses physic, as it is to give it on every occasion, as some do. Neither is it necessary for horses to be bled and physicked every spring and autumn, if they be in perfect health and the less so, as at this time they are generally weak and stout from the change going on in their coats. Nor is it always necessary to give horses physic when they come from green or a straw yard provided the change from the one state to the other be very moderately brought about. But on such a removal, it certainly expedites all the phenomena of condition (6423), and much horses are less likely to afterwards fall in pieces as it is termed (6494). In various morbid states physic is particularly useful, as in worms, hide-bound from too full a habit, &c. &c. It is not advisable to physic horses in either very cold or very warm weather. Strong physic is always hurtful all that physic can do is as well operated by a mild as by a strong dose, and with infinitely less hazard. No horse should be physicked whose bowels have not been previously prepared by mashing for two days at least before. By these means the physic will work kindly and a moderate quantity only is requisite. Most of the articles put into the purging balls for horses, to assist the aloes, are useless. Jalap will not purge a horse, nor rhubarb either. Aloes are the only proper drug to be depended on for this purpose, and of all the varieties of aloes the socotrine and Cape are the best. (*See Pharm.* 6584.) Barbadoes aloes are also not improper, but are thought more rough than the socotrices. For formulae of purging balls, see *Pharm.* 6585. *Alonso* gives the following as the process:—

6535. *Physicking process.* The horse having fasted an hour or two in the morning from food, but having had his water as usual, give him his purge, and two hours after offer him a little chilled but not warm water, as is often done, by which horses are disgusted from taking any. It may be here remarked that in the particular much error is frequently committed. Many horses will drink water with the chaff taken off, provided it be perfectly clean, and do not smell of smoke from the fire, kettle, or outcrop, but few very few will drink warm or hot water and still fewer if it be in the least degree greeny or stinky.

After the bull has been given two hours, a warm bran mash may be offered, and a very little hay. He should have walking exercise as usual, moderate schooling, and altogether he should be kept rather more warm than usual. At noon mash again, and give a little hay which should be repeated at night, giving him at intervals chilled water. On the following morning the physis may be expected to work; which if it do briskly keep the horse quiet, but should if not move his bowels, or only relax them, walk him quietly half an hour which will probably have the desired effect. Continue to give mash and warm water repeating them every two or three hours to support him. When physis grips a horse, give him a cyrtus of warm water and hand-rub the belly as well as walk him out. If the griping grows severe, give him four ounces of gin in half a pint of sound ale, which will soon relieve him. On the next day the physis will probably set, but should it continue to work him severely pour down some boiled starch; and if this fail, turn to the directions under diarrhoea. (6573.) The horse should return to his usual habits of full feeding and full exercise by degrees, and if more than one dose be to be given, a week should intervene. It is often requisite to make the second and third doses rather stronger than the first. A very mild dose of physic is likewise often given to horses while at grass in very warm weather, and without any injury. When worms or skin foulness are present, and mercurial physic is deemed necessary it is better to give two drachms of calomel in a mash the previous night, than to put it into the purging ball.

#### SUBJECT 7. Castration, Nicking, Docking &c.

6565. The operations of castration, docking, nicking, and that of cropping (which is now seldom practised) all require the assistance of a veterinary surgeon, and it is only necessary to remark of them, that the after treatment must be the same as in all other wounds. To avoid irritation, to preserve a cool temperature and a moderate diet, and if active febrile symptoms make their appearance, to obviate them by bleeding, &c. &c. It likewise is proper to direct the attention of the agriculturist who attends to these matters himself, that the moment the wound following any of these operations looks otherwise than healthy, locked jaw is to be feared, and no time should be lost in seeking the best assistance that can be obtained. (6482.)

#### SUBJECT 8. Bleeding

6567. Bleeding is a very common and to the horse a very important operation, because his inflammatory diseases, on account of the great strength of his arterial system, run to a fatal termination very soon and can only be checked in the rapidity of their progress by abstracting blood which diminishes the momentum of circulation. Bleeding is more particularly important in the inflammatory diseases of the horse, because we cannot, as in the human frame, lower the circulation by readily nauseating the stomach. Bleeding also lessens friction particularly in the young and plethoric, or those of full habit. Hence we bleed in manner of the boy who has a locked jaw, &c. with good effect. Bleeding is general or topical. General, as from the neck, when we mean to lessen the general momentum. Topical, when we bleed from a particular part, as the eye, the plate vein, the toe, &c. Most expert practitioners use a large lancet to bleed with, and when the habit of using it is acquired it is by far the best instrument, particularly for superficial veins where a blow might carry the steam through the vessel. In common hands the steam (fig. 6568.) as the more general instrument, is best adapted to the usual cases requiring the agriculturist's notice. Care should

6568

however be taken not to strike it with vehemence and the hair being first wetted and smoothed down, it should be pressed close between the hairs, so that its progress may not be impeded by them. A ligature should be first passed round the neck, and a hand held over the eye, unless the operator be very expert, when the use of the fingers will dispense with the ligature. The quantity of blood taken is usually too small. In inflammatory diseases a large horse, particularly in the early stage of a complaint, will bear to lose eight or ten quarts, and half the quantity may be taken away two or three times afterwards. If the violence of the symptoms seem to require it, and the blood should be drawn in a large stream to do all the good it is capable of. After the bleeding is finished, introduce a sharp pin, and avoid drawing the skin away from the vein while pinning, which lets the blood escape between the vein and skin. Wrap round a piece of tow or hamp, and next day remove the pin which might otherwise inflame the neck. In drawing blood, let it always be measured, letting it fall on the ground prevents the ascertaining the quantity. It also prevents any observation on the state of the blood, which if it form itself into a cup-like cavity on its surface, and exhibit a tough yellow crust over its cavity, it betokens an inflammatory state of body that will require further bleedings, unless the weakness forbid. After the bleeding, it now and then happens, from rusty lancets too violent a stroke with the blood stick, or from drawing away the skin too much while pinning up, that the orifice inflames and hardens, and ichor is seen to ooze out between its edges. Immediately this is discovered, recourse must be had to an able veterinary surgeon, or the horse will lose the vein, and perhaps his life.

#### SECT. VII. Veterinary Pharmacopoeia.

6566. The following formulae for veterinary practice have been compiled from the works of the most eminent veterinary writers of the present day as Blaine, Clark, Laurence, Peel White &c. and we can from our own experience also, confidently recommend the selection to the notice of agriculturists, and the owners of horses in general. It would be prudent for such as have many horses, and particularly for such as live at a distance from the assistance of an able veterinarian to keep the more necessary articles by them in case of emergency; some vendors of horse drugs keep veterinary medicine chests and where the compositions can be depended on, and the uncompounded drugs are genuine and good, one of these is a most convenient appendage to every stable. The best arranged veterinary medicine chest we have seen was in London, at the veterinary laboratory of Youatt of Nassau Street, Middlesex Hospital.

6568. The veterinary pharmacopoeia for some colic, and sheep has been included in the arrangement. When any speciality occurs, or where distinct recipes are requisite, they have been carefully noticed; it will therefore only be necessary to be kept in mind, that with the exception of acid substances, as mineral acids, &c. which no cattle bear with equal impunity with the horse, the remedies prescribed require about the following proportions:—A large ox will bear the proportions of a moderate-sized horse; a moderate-sized cow something less; a calf about a third of the quantity; and a sheep about a quarter; or at most a third of the proportions directed for the cow. It is also to be remarked, that the degrees in strength in the different recipes are usually regulated by their numbers, the mildest standing first.

##### 6569. Colic.

Levigated nutmeg ʒ 4 drachms.  
Tincture of turpentine ʒ 4  
Flavour of ginger each half an ounce.

Or  
Cream of tartar ʒ 4  
Rose, of each half an ounce.

6570. Colic.  
Levigated nutmeg ʒ 4 drachms.  
Tincture of turpentine ʒ 4  
Give in mash, or in corn and bran.  
Milk whey, every night, or twice twice a day with honey.

##### 6571. Tracheitis.

Opium ʒ 1  
Must be mixed in powder, of each ʒ 1 drachm.  
Oak bark in powder, ʒ 4 drachms.

Wheat's bark, in powder, 3 drachms.  
Gum arabic, 30 grains, and a half drachm.  
Mullein, do., 3 drachms.  
Mullein oil, 10 grains.  
Mullein oil, 10 grains, and give a dose.

White vitriol, 1 drachm.  
Ginger or pepper ground, 3 drachms.  
Powdered sugar, half an ounce.  
Ale 3 ounces. Mix, and give as a drink.

Ale, 10 grains.  
Ginger, 1 ounce.  
Mix and give to much or continued  
care slightly.

6542. *Adventitious Powder for Stomach,  
Lungs, or Coughing.*

Powdered hyssopus, 1 drachm  
Dry opium, half a drachm.  
Powdered chalk, 1 ounce.  
Baked starch, 1 pint.  
Heat 4 ounces; boiled in  
water, 6 ounces.  
Baked starch 4 ounces.  
Powdered starch 1 drachm.

The following has been very strongly  
recommended in some cases, for the  
heat of lungs and cattle —  
Ginger's milk, 1 ounce.  
Rye oil, 1 ounce.  
Green vitriol, 4 grains.  
Ginger, half pint.

When the heat or swelling of all ap-  
pendages to the stomach or rectum, the  
following drink should be first given —  
Ginger oil, 4 ounces.  
(Rhubarb) (Ground) 2 ounces.  
Powdered starch, half a drachm.  
Powdered opium, 4 grains.  
Ale, 1 pint.

6543. *Adventitious Balm for Stomach or Pan-  
creas.*

Cinnamon (Japan earth), half an ounce.  
Aloe powder, half drachm.  
Rhubarb of roots, 1 ounce.  
Ginger of roots to make a ball.

6544. *Adventitious Paste for Throat, Pan-  
creas, and in the Feet, &c.*

Prepared columbin.  
Vaseline, of each half an ounce.  
White vitriol.  
Ale, of each half a drachm.  
For 2 ounces milk.

6545. *Adventitious Wash for Coughs in the  
Bovine, Canine, Equine, &c.*

Sugar of lead, 2 drachms.  
White vitriol, 1 drachm.  
Strong infusion of oak or elm bark, 1  
pint milk.

Green vitriol, 1 drachm.  
Bacon of milk, half a pint.  
Mix, and wash the parts three times  
day.

6546. *Powder for Coughs, &c.*

Prepared columbin, 1 ounce.  
Rhubarb of roots, powdered.  
Rhubarb of roots, 2 ounces.  
Rhubarb of roots, 2 ounces.  
Mix, and put whole grains and dab the  
moist surface of the nose frequently.

6547. *Adventitious Paste for Stomach.*

Prepared columbin.  
Rhubarb of roots, 1 ounce.  
Vaseline, of each 2 ounces.  
Vaseline, of each 2 ounces.

To the above, if more strength be re-  
quired, add of starch and vaseline each  
1 drachm.

6548. *Adventitious Wash for the  
Stomach.*

Corrosive sublimate, 1 drachm.  
Spirit of wine or brandy, 1 ounce.  
Milk water, 10 ounces.

Boil the sublimate in a mortar with the  
spirit, till dissolved, then add the water.  
This is a strong preparation, and has often  
proved useful in very bad cases of  
stomach, which have resisted all the most  
violent.

6549. *Mixture.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

When the above latter articles together  
and when not too hot, stir in the Spanish  
oil.

6550. *A strong clear Mixture, but not pro-  
per to be used in Fever or inflammation,  
or of the Lungs, Stomach, &c.*

Corrosive sublimate, 1 ounce.  
Oil of vitriol, 1 ounce.  
Rhubarb, 1 ounce.  
Rhubarb, 1 ounce.

Oil of turpentine, 1 ounce.  
Mix the milk with the lead or oil  
of vitriol with an ounce of water gradually,  
and gradually add the sublimate to the milk  
till it is nearly white, and then gradually re-  
move the vitriol, and when beginning to  
heat, add the powder gradually until  
thickened.

6551. *A universal Mixture for Syphilis, Sp-  
ring, and Rheumatism.*

Of either of the above, 4 ounces.  
Corrosive sublimate, finely powdered, half  
a drachm.

6552. *Strong Liquid Mixture.*

Spanish Mixture in green tea, 1 ounce.  
Oil of turpentine, 1 ounce.  
Oil of turpentine, 1 ounce.

Olives oil, 3 ounces.  
Stir the above in the turpentine three  
times, strain off and add the oil.

6553. *Mild Liquid or Soothing Mixture*

Of the above, 1 ounce.  
Oil of turpentine, 1 ounce.  
Oil of turpentine, 1 ounce.

6554. *Chloride, a Laxative one*

This great or broth, 5 quarts.  
Rhubarb or common salt, 4 ounces.

6555. *Chloride for Coughs.*

Mash two moderate-sized onions.  
Pour over them oil of turpentine, 2 ounces.  
Cinnamon, or pepper, half an ounce.  
This great, 4 quarts.

6556. *Non-Milk Chloride*

Thick great, 3 quarts.  
Strong wood oil, 1 quart.  
Oil of turpentine, 1 quart.

6557. *Adventitious Chloride*

Tripe liquor or milk boiled in milk 3  
times.  
Baked starch, 2 pints.  
Lard, 1 pint.

6558. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6559. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6560. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6561. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6562. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6563. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6564. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6565. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6566. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6567. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6568. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6569. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6570. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6571. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6572. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6573. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6574. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6575. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6576. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6577. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6578. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6579. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6580. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6581. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6582. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6583. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6584. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

6585. *Chloride for Coughs.*

Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.  
Crushed alum, 1 ounce.

3284.  
Alum, powdered, 20 drachms.  
Oil of turpentine, 1 drachm.  
Beeswax.

Alum, powdered, 20 drachms.  
Oil of turpentine, 1 drachm.  
The shoe may be heated with turpentine to a warm effluvia during the heating, the oil of turpentine. All parts of the shoe are of yellow, white, etc. are uniform, and often heated additional.

3285. *Liquid Purg*  
Rhubarb, sliced, 5 ounces.  
Clover oil, 4 ounces.  
Water, 10 ounces of alum, 5 ounces.  
MIX. The watery mixture of alum is made by heating powdered alum with the juice of egg, adding water by degrees; by some means half a ounce of alum may be suspended in eight ounces of water, and such purg is useful when a tail cannot be got down, as in partial locked jaw.

3286. *Building mixture for Pale feet*  
Camellia oil, 1 drachm.  
Yellow lead, 4 ounces.  
3287. *Foot dressing*  
Hemp and cow dung, each about 2 lbs.  
Tar, half a pound.

3288. *Wash for curing and drying*  
Potash, or green ash, 4 dr.  
Lemon juice, 1 drachm.  
Water, 1 pint.

3289. *Wash for ulcers*  
Camellia oil, 5 drachms.  
Spirits of wine or brandy, 1 ounce.  
Decoction of tobacco.  
Dissolve the solids in the spirit, and then add the decoction.

3290. *Medicine for Hoofing*  
Turner's ointment, 4 ounces.  
White vitriol, powdered, half a drachm.  
Lard, 4 ounces.

3291. *For Singeing*

Turner's ointment, 2 ounces.  
White vitriol, 1 drachm.  
Yellow lead, 5 ounces.

3292. *For Singeing*

Rubbing cream, 5 ounces.  
Lard, 10 ounces, 5 drachms.  
Flour, 1 ounce, 5 ounces.  
Lard, 1 ounce.

MIX, and dress with every morning.

3293. *For Red or Hot in Hoof, Stiffness, sore and Swelling in Hoof, and Red Swelling and Swelling in Hoof in general*

Campbell, 1 drachm.  
Sugar of lead, half a drachm.  
Mullein ointment, 1 ounce.

SECT. VIII. Shoeing of Horses.

§ 3294. *The importance of the subject of shoeing to the agriculturist is sufficiently attested by the immense number of inventions which the ingenuity of philosophers and artists are every day devising to render the system complete.* Almost every veterinary professor has his favourite shoe, and we find one of the most ingenious of the present day endeavoring to force on our notice and introduce into our stables, the French method which with the exception of the mode of nailing on, White observes, is the very worst he ever saw. The French shoe (fig. 339 a) has a wide web towards the toe and a concave above and convex below (b) on the ground surface, by which neither the toe nor heel touch the ground (c). But the horse stands pretty much in the same way with an unhappy cat, shot by unlucky boys with walnut shells. But as Blaine observes, in reference to these inventions, "No one form of foot defence can be offered as a universal pattern." It is, he continues, plain that the principles of shoeing ought to be those that allow as little departure from nature as common senses will justify. The practice also should be strictly consonant to the principles, and both ought to consist, first, in removing no parts but those which if the bare hoof were applied to natural ground, would remove of themselves. Secondly, in bringing such parts in contact with the ground (generally speaking) as are opposed to it in an undisturbed state, and above all, to endeavour to preserve the original form of the foot, by framing the shoe thereto, but never to alter the foot to the defence. The shoe at present made at the forges of the most respectable smiths in the cities and large towns throughout the kingdom if it have not all the requisites, has however by degrees, been so improved, that with a few additional directions rather difficult to direct or adopt, it is the one we shall hold up as the most eligible for general shoeing. It is not that a better might not be offered to notice and, in fact, such a one we shall present to our readers, but so averse are the generality of smiths from having any improvements forced on them, and so obstinately determined are they to adhere to the forms handed down to them by their forefathers, that their stupidity or malevolence, or both, frequently makes the very movement itself, when seemingly suggested in a course of irreparable injury. It is for these reasons we would recommend to agriculturists in general a modified shoe of the common stamp.

§ 330. *The improved shoe for general use (fig. 340) is rather wider than what is usually made. Its nail holes (a) extend no further towards the heel than is actually necessary for security by which the expansion of these parts is encouraged, and contraction is avoided. To strengthen the attachment, and to make up for the liberty given to the heels, the nails should be carried around the front of the shoe (c). The nail holes, on the under or ground surface of the shoe (a), are usually formed in a gutter technically called the *falling*, but in the case of heavy treading powerful horses this gutter may be omitted, or if adopted, the shoe is that part may be steered. The web should be quite even on the foot or hoof surface (b), and not only be rather wider, but it should also have rather more substance than is common from half an inch to five eighths in thickness, according to circumstance, horse a fair proportion when it is less it is apt, in wearing, to bend to pressure and force out the clinch. A great error is committed in setting shoes out so much wider than the heels themselves, this error has been devoted to correct another which has been that of letting horses go too long without shoeing in which case, if the heels of the shoe were not too wide originally, as the foot grew they became too wide within the heels and were thus bruised and produced corns, but as we will suppose that few will wish to enter into a certain error to avoid an uncertain one, so we recommend that the heels of the shoe should stand only wide enough to prevent the expansion of the quarters pushing the heels of the foot over the outer edge of the heels of the shoe for which purpose, if the iron proper rather less than a quarter of an inch, instead of three eighths, or even half an inch as it frequently does, many advantages will be gained. Whoever attentively examines a shoe well set out at the heels, as it is termed, will find only one third of the flat surface protecting the heels, the remainder projects beyond, and serves but to form a shelf to lodge dirt on, or as a convenient clip for another horse to tread on, or for the wearer to cut his own legs with, or to afford a more ready hold for the action of clays grounds to jump off the shoe by. The heels of the common shoe are likewise not in general sufficiently long for the protection of the foot and which defect, more than a want of width, causes the tendency to press on the crust of the heels. It is further to be observed, that if the decreased width of the outer standing of the heels, and the increased width of the web, should make the inner angle of the shoe heel in danger of interfering with the frog, the corner may be taken off. In shaping this shoe, it may be revealed, or left plain on both surfaces or rather nearly so, for it is usual with most smiths to thin it in some degree towards the inner edge. This shoe is applicable to most feet, is easily turned, and so much, in country places is all that can be expected.*

§ 331. *The superior effect of last shoeing would only require to be known to excite every endeavor to obviate them; and there are some circumstances in the more common shoes of country smiths that ought to be avoided.*

to be impressed on the mind of every agriculturist, and guarded against by every one who possesses a horse. It is too frequently observed that the ground side of their shoe is convex, and that the lowest rim, when the foot is on the ground, is the lowest part on which it is evident the weight must first press; and by which pressure, the crust will be forcibly thrust on the extreme edge of the shoe; and the only resistance offered to its being forced from it, depends on the nails and claunches, instead of its just application to the ground, and the support derived from the uniform pressure of the whole. Every shoe should therefore be perfectly level on its ground surface; nor should any shoe be put on that has not been tried on a piece of iron purposely made for such trial, which irons are kept in some smithies, but are absent from too many. The substance of the shoe should be the same throughout, forming two parallel lines of upper and under surface, in plain language, the heels, instead of being chiselled as is too frequent, should be the exact thickness of the top. Neither should the width at the heels diminish in the proportion it usually does, on the contrary for a perfectly formed foot, the web should present a uniform width throughout.

520. *Particulars in form of feet, difference in color, weight, and uses of horses, will necessarily make deviations in the form and substance of shoes.* The very shoe recommended may be considered as a variation from what would be immediately necessary were the feet generally perfect; but it is to be considered that there are but very few feet but what have undergone some unfavorable alteration in their form, which makes them very sensible to concussion. It is for this reason, therefore, that it is recommended that a shoe be used, for general purposes, somewhat wider and thicker than the common one. In weak, tender, flexible feet, it will be found particularly advantageous; and here the benefit of wide heels to the shoe will be most apparent. Good as the roads now are, yet most horses are occasionally subjected to travel on bad ones. I have known the addition of one, or at the most, two ounces to each shoe is nothing, but the ease to the horse, and its easier covering, as well as support, is incalculable. In very young, very light, and very firm feet, the width and substance may be somewhat diminished at pleasure, and particularly in situations where the roads are uniformly good, but a very long and extensive experience has assured us, that the shoe portrayed is one well calculated to meet the ordinary purposes of travelling, and the present state of the art of horse-shoeing.

521. *The shoe on the present plan (Fig. 541), would be found to unite all the perfections of the modern English improvements, with some derived from our neighbors the French.*

What has since been called a *scanted shoe* was introduced by Ousey, but from the obscurity and ignorance of smiths, as it could not be brought into general use, it became little thought of, until revived by Clark of Edinburgh by whom it was patronized and recommended. It finally was taken up by Moncreff, and has ever since attracted some attention, and continues to be forged in some shops where the work is superiorly done, and where the employers have liberality enough to pay for such work, and judgment enough to discriminate between its advantages and those of the common shoe. If to this shoe were added the French mode of fastening it to the foot, we think the improvement would almost shut out all others. On examining the figure it will be seen that this shoe presents a flat surface opposed to the ground (a), but a concave one towards the sole (b) but that this concavity does not begin, as in some scanted shoes, near the outer edge, but embraces two thirds only of the web, leaving by this means a sufficient surface for the crust, but the beveling is not intended to reach the heels; it slopes short of them (c) leaving the web at this part plain for the heels to rest upon. The great advantages of this scanted are, first, that as the crust rests on a flat surface instead of an inclined plane, as most of the common forged shoes present, so its position is maintained entire, and the inclination to contraction is in a great degree avoided. The nailing on of this shoe would recommend it to be after the French method, which consists in conical nail holes, punched with a square counterbore (d), into which are received conical nails (e) which exactly fill up the counterbore; by which means so long as any part of the base of the nail remains, the shoe must be held firmly on, and which is not the only advantage gained; for the nail holes being obliquely formed, and at some distance from the outer rim, act less detrimentally on the crust of the foot.

522. *To prepare the foot for the application of the shoe is also an important consideration.* Avoid taking off more than one shoe at a time, otherwise the edges of the crust become broken away. Observe that the clinches are all carefully removed. Let the rough edges of the crust be rasped away after which, the sole should be pared throughout until a strong pressure with the thumb can produce some yielding, too strong a sole tends to heat and contraction, too weak a one will not require paring. In this paring imitate the natural arch of the sole as much as possible. The line of concavity should not begin, as it usually is made to do, from the extreme margin of the foot, but should begin from the inner line of the crust only; by which means the crust, or outer wall of the hoof, will have a firm bearing on the flat surface of the shoe. Let no heated shoe be applied to correct the inequalities that may be left, unless it is for a moment, only to observe, but not burn them; but still more carefully avoid putting a plane shoe on an uneven foot. The portion of sole between the bars and quarters (Fig. 538. d) should be always pared out as the most preventive against corns. The heels also should be reduced to the general level of the foot, never allowing their height to serve as an excuse for being left; neither suffer the inner heel to be lowered more than the outer. After all the rest has been done, the frog should be so trimmed as to remain on an exact level with the returns of the heels, and no more. The custom of taking away the point or angle of the horny inflexion of the heels, under the false term of opening the heels, is to be carefully avoided. Let all these operations be performed with the drawing knife. The butters should never be allowed to come near the foot of any horse but the largest and coarsest of the cart breed.

523. *The shoe for the hind feet are somewhat different to the fore, being a little square at the toe for about an inch; to which squariness the hoof is to be also adapted by rasping it slightly so avoiding, how ever, to do it injuriously.* By this made a steady point of bearing is afforded to the hinder feet in the great exertions they are often called upon to make in galloping, leaping &c. They are when thus formed, less liable, also, to interfere with the fore shoes by striking. When horses stand or over-reach very much, it is also common to square, or rather to shorten the toes of the hinder shoes; but not to do so by the horn by which, the hoof meets the middle of the fore shoe instead of the shoe itself; and the unpleasant noise of the strains or click of one foot against the other is avoided.

524. *Particulars which necessarily occur in shoeing.* The bar shoe (Fig. 525.) is the most important variety, and it is to be regretted that so much prejudice prevails against the use of this shoe, which can only arise from its comparatively recent origin in the country. As a substance to work this foot it is invaluable, as it removes a part of the pressure from the heels and quarters, which can ill bear it, to the frog which can well bear it; but a well formed bar shoe should not have its barred part raised like an edge behind, but such part should be of one uniform thickness throughout the web of the bar which, instead of being the narrowest, should be the widest part of the shoe. The thickness of the bar should be greater or less (a) as to be adapted to take only a moderate pressure from the frog. When the frog is altogether elevated away by thrust, the bar may be altogether plain, but this form of shoe is still the best for those cases, as it prevents the tender surface from being wounded. In corns this shoe is invaluable, and may then be so made as to fit off the affected part, which is the great desideratum in corns.

525. *The banding shoe is made lighter than the common one, and it is of consequence that it is*

made to sit as flat to the foot as it can safely do without pressing on the sole; by which the great action in clayey grounds is much lessened. Hunting fore-shoes should also be as short as the heels are consistent with safety to the foot, to avoid the danger of being pulled off by the hinder shoe. Nor should the web project at all. It is the custom to turn up the outer heel to prevent slipping, which is done sometimes to both fore and hind feet, and sometimes only to the latter. As this precaution can hardly be avoided in hilly slippery grounds, it should be rendered as little hurtful as possible by making the tread equal, to which purpose, thicken the inner heel and turn up the outer. This is better than lowering the outer heel to receive the shoe, which still leaves both the tread and foot uneven.

842. *Grass shoes or tips* are very short pieces placed on the toe alone, in horses turned to grass in summer at which time they are essentially necessary to guard the fore feet, which otherwise become broken away and irretrievably injured. They should be looked at occasionally to see that they do not indent themselves into the sole.

843. *Front shoes* (fig. 843) have the ends turned up to prevent the foot from sliding, unless the turning up or calkin be hardened, they soon wear level and require to be renewed, to the injury of the foot by such frequent removals. To remedy this, many inventions have been tried, one of the best of these is that of Dr. Moore, in which the front clip is made distinct and moveable by means of a female screw (a) worked in it to which a knob or wedge (c) and male screw (d) are adapted, a key (e) being used for fixing or removing it.

843. *High calkins or turn-ups*, however objectionable in general shoeing, yet, in precipitous countries, as those of Devonshire, Yorkshire, and Scotland, &c. are absolutely necessary for their draught horses. It greatly obviates the evils of uneven pressure if a calkin be also put to the toe and it would be still better were these calkins scaled, particularly the fore ones.

844. *The shoeing of diseased feet* is necessarily very various, and is too often left to the discretion of the smith, by which the evils themselves are greatly aggravated, if he be ignorant. The most prominent alterations for these purposes will be found described under the respective diseases of the feet requiring them.

845. *Horse pattens* are in use by some cultivators who occupy soft or mossy soils. These extended boots are constructed of alder or elm and are fixed to the hoof by means of three links and a staple through each of which passes a leather strap that goes twice round the hoof and is fastened by a buckle. The staple is placed behind the patten which is ten inches one way by ten and a half the other. The links are about three inches in length, and riveted through pieces of hoop iron to prevent the wood from splitting. After numerous trials, it has been found that pattens made in this way answer the purpose better than any other kind. (*Farm. Mag.*)

#### SECT. IX. Criteria of the Qualities of Horses for various Purposes.

6008. *The general criteria of the qualities of a horse* are derived from inspection and trial. His outward appearance among judges affords a pretty just criterion of his powers, and a moderate trial usually enables the same judgment to decide on the disposition to exercise such powers.

6010. *The criteria of a horse derived from his colour* have been already noticed. (6008.) As a general principle dark are preferable to light horses except in the instance of black, which has fewer good horses within its range, particularly in the lighter breeds, than any other. Grey horses are also, in some degree, an exception to the rule for there are many good greys. Bay and brown are always esteemed colours.

6011. *The criteria of action* are derived from a due consideration of the form generally, and of the limbs particularly as well as from seeing the horse perform his paces in hand.

6012. *The criteria of hardihood* are derived from the form of the carcass, which should be circular or barrelled by which food is retained, and strength gained to perform what is required. Such horses are also generally good feeders.

6013. *The criteria of spirit, vigour or mettle*, as it is termed, are best derived from trial. It should always be kept in mind that a hot fiery horse is as objectionable as a horse of good courage is desirable. Hot horses may be known by their disinclination to stand still by their mettle being raised by the slightest exercise, especially when in company. Such horses seldom last long, and under accident are impetuous and frightened in the extreme. A good couraged horse on the contrary moves with readiness as well alone as in company. He carries one ear forward and one backward, is attentive and cheerful, loves to be talked to, and caroused even while on his journey and if in double harness, will play with his mate. Good couraged horses are always the best tempered, and, under difficulties, are by far the most quiet, and least disposed to do mischief.

6014. *The criteria of a race-horse derived from form*, are, that he have the greatest possible quantity of bone, muscle, and sinew in the most condensed form. There should be a general length of parts to afford stretch, scope, and elasticity, with great muscles hardened by condition, to act on the length of these parts advantageously. In particular his hind limbs should be furnished with ample thighs and broad hocks, which should be low set. His fore-arm ought also to be broad, and the knee, like the hock, should be near the ground.

6015. *The criteria of a hunter* are that he have somewhat similar proportions with the racer but with more bulk to enable him to continue his exertions longer and to carry more weight. In him a good opinion is essentially necessary to fit him to go through a long chase and the more, if he be required to hunt more than one or two days in the week. Some light couraged horses will do one day's hunting work a week very well, but knock up at noon. The hunter should be well formed in his joints, and well let down in his thighs to propel him forward in his gallop, and give him strength to rise sufficiently to cover his leaps. It is also of great use to a hunter to be a good trotter, many such horses, when fatigued, break out of the gallop and relieve themselves by trotting, particularly over heavy ground.

6016. *The criteria of a hackney*. If it be necessary that the hackney be well formed behind to give him strength, and to propel him forward, it is even of more consequence that he be well formed before; and in this kind of horse the hind parts are in some measure subordinate to the fore, as safety is predicated to speed. The head in the hackney should be small, and well placed on a neck of due length and substance to make a proper support for the bridle, and that proper resistance to the hand, so pleasant to the seat, and

as necessary for use and safety. The shoulders should be oblique and well furnished with muscle, but not heavy; and the withers in particular should be high. The elbows should be turned rather out than in, and the legs should stand out straight, and by no means fall under the horse, or it betokens a stumbling gait. The pasterns should neither be too oblique, which bespeaks weakness; nor too straight, which wears the horse out, and is unpleasant to the rider. The carpus should be round, or the horse will be weakly and weak; the joints straight, wide, and ribbed horse; the thighs of good substance; and although the hocks are hammed, or having the hocks turned forwards, is defective in beauty it often bespeaks a trotter.

617. The criteria of a steady horse are, that he have considerable extension of bulk or sin, to enable him to carry weight, with good canvas to allow him to feed coarsely, and yet thrive at picket or on service. He should have also liberty of action, but great speed is not requisite. The best cavalry horses are those swiftest of the united properties of hackneys and very light draught horses.

618. The criteria of road horses for gait, draught, or coach, chariot, stage and post chaises, &c., are derived from the immediate purposes for which they are intended; as requiring either strength or speed in greater proportion. To make them safe, the fore-hand should rise, the back should be straight, the step should be short but quick, which requires less. As they approach the hunter in form, they are best fitted for quick work, and as they resemble the best kind of light agricultural horses, they are calculated for heavy draught, as coaches, &c. But in all, a portion of blood gives courage, durability and condenses strength into lessened bulk, by which activity is gained. It is of great consequence to a coach-horse that the neck and head be so formed as to be enabled to rein-in well to the bridle.

619. The criteria of a day-horse are, that he be very broad breasted, and muscular and thick in the shoulders, which should not lie backward. Nor should the fore-hand be up, as recommended in the road-horse, for by holding up their heads, such horses may be choked by the collar as they would, if so formed, draw too much by the throat, and their wind being thus stopped, would be in danger of falling down. The neck of a day-horse is not the better for being long, and the head should be proportionate to it. Like all horses, he should be short in the neck, and good strong hocks. He ought to be thick in his thighs, and large in bone; but above all, he ought to be a steady collared horse, with courage to make him true to a service pull, and yet, without a hot fiery spirit to make him fretful.

620. The criteria of a waggon horse are, in some respects, different from those of the day-horse. He should be more weighty and altogether larger. Rapidity of motion is greatly subordinate, in the heavy stage-waggon, really seen in all collar work; nothing is gained, from the momentum of the dragged mass, which, the instant the pull ceases, stands still. The waggon horse should be patient in the extreme, willing to lie to his collar up-hill and yet settle into his share of work on level ground. As his exertions are constant, it is of the greatest consequence that he be a good feeder.

621. The criteria of a horse peculiarly adapted to the labours of agriculture are thus given by Calley. — His head should be as small as the proportion of the animal will admit; his nostrils expanded, and muscular; his eyes cheerful and prominent; his ears small, upright, and placed near together; his neck, rising out from between his shoulders with an easy tapering curve, must join gracefully to the head; his shoulders, being well thrown back, must also go into his neck (at what is called the points) unperceived, which perhaps facilitates the going much more than the narrow shoulder; the arm, or fore-thigh, should be muscular, and tapering from the shoulder to meet a fine, straight, slender and bony leg; the hoof circular and wide at the heel, has chest deep, and full at the girth; his loins or ribs broad and straight and bony round; his hips or hooks by no means wide, but quarters long, and the tail set on so as to be nearly in the same right line as his back; his thighs strong and muscular; his legs clean and fine-boned the leg-bones not round, but what is called *lathy* or *flat*.

622. The chief points in a *forward* *carriage* horse, as the opinion of the author of the *New Farmer's Calendar* are, a neck not long, but rather flat than round and grumpy; fore-legs even, not too distant; wide chest, strong but not high shoulders; considerable length of waist supported by a wide loin; quarters full, and rather raised; strong muscular thigh, mus, fifteen hands one inch to sixteen hands high. Being somewhat forelow gives them an advantage in draught and a moderate length of waist insures speed in the walk.

623. The horse used in *hackneying* according to the writer of the *Experiment Farmer* ought to be larger but in other respects like the road horse and, instead of walking two or three miles an hour be able to walk four or five. In that case he would be able both to plough more land in a given time, and work in the cart or waggon with more despatch, when wanted. In harvest time, a nimble and strong horse is valuable. In drawing manure into the field, or corn to the market, the farmer will also find his account in strength and activity. For, as five draught in all these cases is light one way such horses would do their business with speed. The small farmer need not with this kind of horse keep an idle one; he might carry his master to market, and plough the remainder of the week.

624. In a horse for the plough, according to Brown, both strength and agility are required, a dash of blood, therefore, is not disadvantageous. It is not also that confers strength the largest horses being often comest worn out. A quick even step, an easy movement, and a good temper, are qualities of the greatest importance to a working horse; and the possession of them is of more avail than big bones, long legs, and a funny carriage. To feed well is also a property of great value and this property as all judges know depends much upon the shape of the barrel, depth of chest, strength of back, and size of the hips or hooks with which the animal is furnished. If straight in the back and not over short, high in the ribs, and with hocks close and round, the animal is generally hardy capable of undergoing a great deal of fatigue, without lessening his appetite, or impairing his working power; whereas horses that are chop pointed, flat ribbed, hollow backed, and wide set in the hocks, are usually bad feeders, and soon done up when put to hard work.

625. The criteria of a horse's age are derived from the appearance of the teeth. According to La Fosse the younger, there are three appearances. The horse is foaled with six molar or grinding teeth in each jaw (fig. 844. a) the teeth or twelfth day after the two front nippers (c) appear above and below and in

fourteen or fifteen days from this, the two intermediate (b & d) are pushed out the corner ones (c & e) are not out till three months after. At two months the incisors or nippers are on a level with each other the front less than the middle, and these again less than the corners; they at this time have a very sensible cavity (d). At twelve months the central incisors are removed, and the animal appears with four molar teeth on each side, above and below, these of the *impermanent* or *cutters* and one permanent or *horse* tooth at eighteen the cavity in the nippers is filled up, and there are five grinders, two of the horse and three permanent; at two years (fig. 844. f), the first of the colt's molar teeth in each jaw above and below are displaced; at two years and a half, or three years, the front nippers fall and give place to the permanent ones; at four years and a half the middle nippers are likewise removed, at which period the central molar teeth at four years the horse is braced with six molar teeth five of his own set, and one of his last; at four years and a half the corner nippers of the colt fall and give place to the permanent set

(*fig. 844. c*), and the last temporary grinder disappears at five years old the tusks in the horse usually appear at five and a half they are completely out, and the internal wall of the upper nipper, which

845

before was incompletely formed, is now on a level with the rest at this period the incisive or nippers have all of them a cavity formed in the substance between the inner and outer walls (*fig. 844. f*) and it is the disappearance of this that marks the age at six years these in the front nipper below are filled up (*fig. 845. c*), the tusks are likewise slightly blunted; at seven years the mark or cavity in the middle nipper is filled up, and the tusks a little more worn (*fig. 845. f*); at eight years old the corner nippers are likewise plain, and the tusks are round and shortened (*fig. 845. g*). In mares, the incisive or nippers alone present a criterion (*fig. 845. e*); at this period the horse is said to be aged, and to have lost his mark; but among good judges the teeth still exhibit sufficient indications. At nine the groove in the tusks is worn away nearly, and the nippers become rather rounded at ten these appearances are still stronger; at twelve the tusks only exhibit a rounded stump, the nippers push forward, become yellow and as the age advances, appear triangular and usually uneven.

655. *M. R. St. J.*, the late professor of the English Veterinary College used to assert, that after eight years the cavities in the anterior or upper incisive teeth are filled up with equal regularity; thus from eight to ten the front ones were filled up, from ten to twelve the two middle and from twelve to fourteen those of the corner; but though some pains have been taken to ascertain this, it does not appear that the disappearance of the cavities in these teeth is attended with sufficient regularity to warrant implicit confidence.

657. To make a colt appear older than he really is, both breeders and dealers very commonly draw the nippers, particularly the corner ones by which means the permanent set which are underneath immediately appear and the animal is thus fitted for sale before he otherwise would be.

658. To make a horse look younger than he really is, dealers perform an operation on the teeth called *belipping* (from the name of a noted operator); which consists in making an artificial cavity in the nipper, after the natural one has been worn out by age, by means of a hard sharp tool which cavity is then burned black by a heated instrument. But no art can restore the tusks to their form and height, as well as their internal grooves. It is, therefore, common to see the best judges thrust their finger into a horse's mouth contacting themselves with merely feeling the tusk. To less experienced judges other appearances present themselves as aids. Horses, when aged, usually become hollow above the eyes, the hoofs appear rugged, the under lip falls, and if grey they become white. In this country where horses are so early worn before the frame is consolidated and where afterwards they continue to be exerted unceasingly on hard roads, it is not uncommon to find a horse at six years old feeble debilitated, and exhibiting all the marks of old age, except in his mouth on the contrary when the animal falls into other hands, at ten or twelve he has all the vigour of youth and his teeth are the only parts that present an indication of age. It is, therefore, more useful to examine the general appearance of the animal than to be guided altogether by the marks in the teeth. A too strict adherence to which, Blaine observes, lead into great error on the subject of the age of horses. The commonly received marks, he says, grant not a criterion of a third of the natural life of the animal, nor of one half of the time in which he is perfectly useful. Many good judges will not purchase a horse for hunting earlier than eight years old and regard him only in his prime at twelve. A gentleman at Dulwich has a monument to the memory of each of three several horses which died in his possession at the age of thirty five, thirty seven, and thirty nine years; the latter of which was suddenly taken off by a fit of colic, having been in harness but a few hours before. Colley mentions a horse of forty five; and an instance lately occurred of one which lived to fifty. Blaine, in continuation draws the following comparison between the relative situations of the state of the constitution, between the horse and man, under the ordinary circumstances of care towards each — The first five years of the horse may be considered as equivalent to the first twenty of a man; a horse of ten as a man of forty; of fifteen as a man of fifty; of twenty as a man of sixty; of twenty five as a man of seventy; of thirty as a man of eighty; and of thirty five as a man of ninety (*See Outlines p. 35*).

#### SECT. X. Breeding of Horses.

659. The general principles of breeding we have already laid down at length (282), and have here to notice what are considered the best practices in the choice of stallions and mares, and in the treatment of the latter during pregnancy. Unfortunately however, much less attention has been paid to breeding horses than to breeding cattle or sheep though, as Brown has observed, a pound of horse-flesh is worth two of that of any other stock and it costs just as much to breed a bad horse as a good one. Every one, an eminent writer observes, exercises some degree of judgment in regard to the stallion but there are few breeders, comparatively who hesitate to employ very ill-formed and worthless mares, and often solely because they are unfit for any thing else than bringing a foal. All the best writers on agriculture reprobate this absurd and unprofitable practice. "In the midland counties of England, the breeding of cart horses is attended to with the same assiduity as that which has of late years been bestowed on cattle and sheep; while the breeding of saddle horses, hunters, and coach horses is almost entirely neglected; or left almost wholly to chance, even in Yorkshire, — I mean as to females. A breeder here would not give five guineas for the best brood mare in the kingdom, unless she could draw or carry him occasionally to market; nor a guinea extraordinary for one which could do both. He would sooner breed from a rip, which he happens to have upon his premises, though not worth a month's keep. But how absurd! The price of the leap, the keep of the mare, and the care and keep of her progeny, from the time they drop to the time of sale, are the same whether they be sold from ten to fifteen or from forty to fifty pounds each." (*Marshall's Economy of Yorkshire vol. II. p. 165*). A little consideration will show this error in a still stronger light, when we consider that united with the characteristic marks common to the breed in general, the progeny of two individuals always exhibits traits of resemblance to each and as the defects are as certainly propagated as the excellencies, so a neglect in being equally careful in our selection of the female as the male parent is actually bespeaking deformity. If being also now and then observed, that a stronger resemblance is borne to the mother than to the father; so the chances of a worthless colt are increased. It having likewise been remarked, that every variety has a tendency to breed back towards its original, so a breed thus constituted can hardly admit of amelioration but remains stamped by its original erroneous selection. These remarks, it is hoped, will encourage our breeders to be less indifferent to the choice of their breeding mares.

660. In those districts where the breeding of horses is carried on upon a large scale and a regular plan, the rearing of stallions forms in some degree a separate branch and is conducted, as in the case of bulls

and tame, in a few content breeders. These stallions, which are shown at the different towns in the vicinity, sometimes sent to be exhibited at a considerable distance, are let out for the whole season, or sold to station men, or kept by the breeder himself, for covering such mares as may be offered, at a certain price per head; and this varies according to the estimation in which the horse is held, and sometimes according to the mare he mares or less of what is called blood. For farm mares, the charge for covering by a stallion of the same kind is commonly about a guinea, with half a crown to the groom; and it is a common practice in the North to agree for a lower rate if the mare does not prove with foal; sometimes nothing more is said in that case than the allowance to the groom.

6531. In choosing any parents, or stallion and mare, regard must be had to the kind of stock desired to be bred. Whatever may be the particular purpose of the breeder, a stallion ought first to possess all the general properties of a good horse, and next the characteristic criteria of the desired stock. The produce, whether a male or female, much more frequently acquires and retains the form, make, make, and disposition of the sire than the dam. On this account, stallions with the least appearance of disease, blemish, or bodily defect of any kind, where there is the slightest probability of its being transmitted to the offspring, should be rejected as improper. And it is even considered by some necessary to descend to the minutiae of symmetry in the head, neck, shoulder, forehand, ribs, back, loins, joints, and pasterns, attending even to a strict uniformity in the form, make, and texture of the hoofs. It is also of importance to ascertain the temper and disposition of both sire and dam, in order to avoid the procreation of vices or imperfections. But provided either parents be free from hereditary infirmities, disorders which arise from accident are of no consequence.

6532. The general proportion required in a breeding mare are a good shape, a gentle disposition, a large carcase conformably to her height, and belly well let down; she must be perfectly free from all sorts of blemishes and defects. The size, frame, bone, strength, and blood, will of course be regulated by the purposes of the breeder.

6533. The mare selected is intended to supply draught colts should, according to the author of the *Synopsis of Horses*, be large-limbed, short-backed, wide-chested, horse-fibred, with a capacious body, her eyes good, and her nostrils large and open; in disposition she ought to be gentle and tractable; of a constitution healthy and vigorous, free from any blemishes either hereditary or acquired. The horse should be bold and spirited, well made, and of a kindly disposition; his constitution should be strong, his temper good, and, in short, neither in mind or body ought he to be contaminated with vices or diseases of any kind, and the good qualities and strength of constitution in the sire and the dam depends, in a great measure, the future welfare of the colt.

6534. The age at which horses should be allowed to breed is not determined by uniform practice, and is liable to depend, in some measure, on the degree of maturity, which in animals of the same species, is more or less early according to breed and feeding. Yet it would seem, in general, to be an improper practice to allow animals of any kind to propagate, while they are themselves in a new unformed state, and require all the attention which their food affords, for raising them to the ordinary use of the variety to which they belong. It may therefore, be seldom advisable to employ the stallion till he is about four years old, or the mare till she is a year older and if the stallion be five also it is better and still more so if he be six or seven. But the greater number of mares left for breeding are not very young, being in many cases not allowed to bring foals till they are in the decline of life, or otherwise unable to bear their full share in cruel labour.

6535. Three months before a stallion is actually employed, he should be fed with sound oats, peas, or beans, or with coarse bread, and a little hay but a good quantity of wheat straw he should be watered regularly and have long continued walking exercise every day but he should not be over-heated. If he be not prepared and put in condition, the colts will be likely to be weakly and the horse himself will become injured, besetting humours, becoming back-winded. If he be put to too many mares, he will not last long; his mane and tail will begin to fall off through weakness, and it will be difficult to get up his flesh again by the next year. The number of mares should be proportioned to his strength, and twelve, fifteen, or at the most twenty are as many as a horse will well serve for in a season. This number indeed, is thought by many too few, and in Suffolk, we are informed on the best authority the stallions serve from fifty to seventy and even eighty mares in a season.

6536. The usual season for the procreative process is from the beginning of April to the beginning of July. The month of June is considered the best season in this country; although from the middle to the end of May is more approved of on the Continent, particularly in Normandy, where the farmers devote much of their attention to this branch of husbandry; and in which especially in regard to useful farm horses, they have succeeded, perhaps, beyond those in any other part of Europe. This difference as to the time when a mare should be allowed to take the horse, in the different countries, is easily reconcilable: a mare goes eleven months and a few days with foal; and the great object with all farmers, where practicable, is to have her covered at such a period as to ensure abundance of grass, and the return of warm and comfortable weather at the period of foaling. An early colt is always to be preferred to one that falls late in the season. It is generally understood, and is an opinion that is believed to be well founded, that a mare may be covered on the ninth day after she has foaled, with a greater degree of success than at any other period. This practice is, of course often followed; but in such cases the mare ought, Doubtless thinks, to be fed in an extraordinary manner otherwise it is impossible she can do justice to her present and her future foal. But modern farmers would probably, he says, come nearer their purpose, were they to follow the example of the Romans, and content themselves with one foal in the two years.

6537. At the season of parturition, there should be a reliable supply of food for the mother and young. The time of covering must, therefore, to be partly regulated by a due regard to this circumstance, and may be earlier in the south than in the north, where grass the most desirable food both for the dam and foal, does not come so early by a month or six weeks. In Scotland, it is not advantageous to have mares to drop their foals sooner than the middle of April; and as the period of gestation is about eleven months, they are usually covered in May, or early in June. But if mares are intended to bring a foal every year, they should be covered from the sixth to the eleventh day after foaling, whatever may be the time; and the horse should be brought to them again nine or eighteen days afterwards.

6538. In breeding horses on a large scale it is easy to contrive so that all the foals may be brought forth at a time when there is plenty of grass. About the end of May the mares are to be put into an enclosure capable of feeding them as long as the stallion is to be with them, or that they are in season. In this enclosure all the mares are to be put together, as well those which are barren as others. The stallion is to be taken out to be taken off, but the first should be left, or the put on to preserve his heat. Then lead him forth, and let him cover a mare twice in hand, to render him more tame and gentle. After this take off the bridle and turn him loose among the rest, where he will become familiar with them, and not one of them will be harmed but when they are in season. There should be a little lodge built up in some part of the enclosure, and peas, beans, oats, hay, and not other good food, put into the manger in it, that the horses may retire into it in the evening hours, and eat what he likes best. He must be shut out, but he must be shut out during the whole time he is with the mares, which is to be about six or seven weeks. Mares that are very fat and green do not hold well; but those which are moderately fat conceive with the greatest success and ease.

6539. To bring a mare in season, it is a common thing to give her a quart of hemp-seed, or twice that quantity, night and morning for eleven days before she is brought to the horse. If she refuse it alone, it may be mixed with beer or oats, and will go down; and if the stallion eat of it, it will serve him also; but it must be remembered that these precautions are unskilful, and often defeat their own purpose. They

are therefore seldom now resorted to among intelligent breeders. Still more improper is it to attempt an early weaning, by injecting stimulating fluids up the vagina as is sometimes done. For when it succeeds, the future progeny seldom surmounts the expectation.

6641. The treatment of a pregnant mare is in general little different from that of any other horse. Mares of draught are worked in summer as usual, and more moderately in the ensuing winter till near the time of foaling when, if the season be somewhat advanced even though the pasture be not fully sufficient for their maintenance, they should be turned out to some grass field near the homestead, and receive what additional supply of food may be necessary under sheds adjoining. It is both inconvenient and dangerous to confine a mare about to foal in a common stable, and still more so to leave her loose in a close stable among other horses; and confinement is not much less objectionable after dropping her foal.

6642. Breeding mares are usually worked through the greatest part of the year, laying them aside only for a week or two before foaling, and during the summer season when giving suck to the young foal. In this way, Brown observes the strength and vigour of the mother is not only weakened, but the size and power of the foal stand a great chance of being diminished, by the exertions of the mother when kept at work. Under these impressions we are led to consider the working of breeding mares as an unprofitable practice. Were they suffered to remain at ease, to roam upon coarse pastures, where sheds were erected in which they might find shelter during inclement weather we are almost certain that their progeny would enter upon action with increased abilities. The expense of a breeding mare kept in this way would not be great, whilst the advantages would be innumerable. In Yorkshire and in those midland counties where the breeding and rearing of horses is better understood than in any other part of the island, they are often worked till the very time of foaling. Great care, however, is necessary in working and managing a mare heavy with foal: an over-heat, too severe exercise, a fright, or a sudden and violent jerk, are very apt to cause an untimely birth, whereby the foal is lost, and the life of the mare very much endangered.

6643. In the mountains of Wales, and in the Highlands of Scotland, the breeding mares are never worked during the summer. They are driven to the hills and mountains at the close of the barley-and-oats season, where they remain till the inclemency of the weather forces them to return for shelter. But their scanty subsistence, the labour they are subjected to in procuring their food, and the moistness and coldness of the climate in the latter part of the season, render both themselves and their progeny of but little value and importance.

6644. Farms consisting chiefly of pasture land unfit for feeding, are the situations where breeding is generally carried on. Arable farmers may breed occasionally, but the inconvenience of wanting any part of their working stock at the time of foaling operates almost as a prohibition to the breeding of horses. The greater number of horses are bred in situations where a small portion of arable land is attached to farms chiefly occupied with cattle or sheep; or where the farms are so small as not to afford full and constant employment to the number of horses that must, nevertheless, be kept for the labour of particular seasons.

## SECT. XI. Rearing of Horses.

6645. Rearing includes the treatment of the foal till it is fit to work, or to be put in training for use, and also the treatment of the mother till she has weaned her foal.

6646. In regard to the treatment of the mare till she has weaned her foal in England, and in the improved parts of Scotland, a mare after having foaled is turned, together with the foal into a pasture field, and is allowed two or three weeks rest, before she is again worked, either in plough or cart. The foal being allowed to suck at pleasure during the time. After having had a few weeks rest, she is again worked in the usual manner, the foal being commonly shut up in a house during the hours of working. In Yorkshire, some farmers are particularly careful not to allow the mare to go near the foal, after her return from labour till her udder has been bathed with cold water and not till most of the milk is drawn from it. These precautions are used with a view of preventing any bad consequences from the foal's receiving over-heat milk. Another practice and which is superior to the above, is also common in Yorkshire, and in many parts of Scotland. — After the foal is a few weeks old, and has acquired strength and agility enough to follow its mother, it is allowed to attend her in the field during the hours of labour, and to suck occasionally. By this means, not only does the foal receive sufficient exercise nor run any prejudicial effect happen from the over-heat state of the milk, as the foal is allowed to draw it off repeatedly and at short intervals; but the little animal becomes hardy, and loses all timidity and afterwards requires less breaking. These may be considered as the general modes of management in these parts of the kingdom mentioned above, during the period while the foal is allowed to suck its dam, which is usually about six months: that is, from the time of foaling till Michaelmas which is the period at which foals are generally weaned, or prevented from sucking. Breeding mares are evidently unable to endure the fatigue of constant labour for some months before and after parturition: this has led a few farmers to rear foals upon cow milk, but the practice is neither common nor likely ever to become so; and as it is a philosophical fact, well established, that all animals partake, in some measure, of the nature of their foster parent, so there is great reason to fear this practice would prove injurious to foals so reared.

6647. In weaning the foal at the end of six or seven months, great care should be taken to keep the mare and foal from the hearing of each other that neither may fret or pine after the other. The best method will be to confine the foal in a small stable by itself which should be furnished with a rack and manger, where it may be fed with clean shaven hay and clean sifted oats, bruised a little in a mill, or chopped carrots, or boiled potatoes. With this management, he will quickly forget his dam, and become gentle and familiarised to his keeper and in fair weather may be suffered to exercise himself in a pasture adjoining to the stable; but this should be only for a little while in the middle part of a sunny day; the tenderness of the young animal rendering it dangerous to keep him out in the night.

6648. The treatment of weaned foals in England, is to put them immediately into a good fresh pasture, where they remain as long as the winter continues moderate. On the approach of winter they are fed with a sufficient quantity of hay, placed in a stable or hovel erected in the field for the purpose, and into which they have free access at all times. The next summer they are put into other pastures, commonly the most indifferent on the farm, where they remain till the beginning of the following winter when they are either allowed to range in the pasture fields, or brought home to the straw yard. The inclemency of the winters in Scotland and the great falls of snow which generally take place, render it necessary always to house the foals there during that season.

6649. During the first winter foals are fed on hay with a little corn, but should not be constantly confined to the stable. For even when there is nothing to be got on the fields, it is much in their favour to be allowed exercise out of doors. A considerable proportion of succulent food, such as potatoes, carrots, and Swedish turnips (oil-cake has been recommended, should be given them through the next winter and beans and peas meal has been advantageously substituted for oats, but which, if allowed in a considerable quantity are injurious to the thriving of the young animal, from their heating and astringent nature.

6650. During the following summer their pasture depends upon the circumstances of the farms on which they are reared. In the second winter they are fed in much the same manner as in the first, except that straw may be given for some months instead of hay; and in the third winter they have a greater allowance of corn, as they are frequently worked at the harrows in the ensuing spring. (General Report of Scotland, vol. II. p. 155.) When about three years old, the author of the *New Farmer's Calendar* advises

feels to be fed all winter with a little corn twice a day with hay, cut straw, &c. Where carrots can be procured, they form a most excellent food for mares of every age, on which they will thrive surprisingly. With the use of carrots, no corn is necessary nor any peculiar regimen against an over-heating effect from a more stimulating diet. Care should, however, be taken to cut them properly allowing a well littered shed, or straw straw-yard. Colts fed at home with green mow, cut during summer should have a daily ration of a common, or elsewhere, the autumn. Yearlings to be carefully kept separate from the milch mares.

653. *The time for gelding colts* is usually the same in both parts of the kingdom, which is, when they are about a year old, although, in Yorkshire, this operation is frequently suspended till the spring of the second year, especially when it is intended to keep them on hand, and without employing them in labour till the following season. Parkinson disapproves of delaying this operation so long, and recommends twisting the colts, a practice well known in the iron-bridges, any time after a week old, or as soon after as the testicles are come down, and this method, he says, he has followed himself with great success (*Farmhouse on Live Stock*, vol. ii. p. 74.) Blaine's remarks on the subject of castration appear worthy of notice. He says, when the breed is particularly good and considerable expectations are formed on the colt, it is always prudent to wait till twelve months. At this period, if his fore parts are correspondent with his hind parts, proceed to castrate. But if he be not sufficiently well up before, or his neck be too long and thin, and his shoulders narrow, he will assuredly improve by being allowed to remain whole six or eight months longer. Another writer suggests for experiment, the spaying of mares, thinking they would work better and have more wind than geldings. (*Marshall's Yorkshire*, vol. ii. p. 102.) But he does not appear to have been aware that this is by no means a new experiment: the Tuscans, who wrote in 1582, speak of gelding sows as a common practice at that period. The main objection to this operation is not that breed mares would become scarce, as he supposes, but that, by impeding them from breeding in case of accident, and in old age, the loss in this expensive species of live-stock would be greatly enhanced. An old or lame mare would then be as worthless as an old or lame gelding is at present.

654. *The rearing of horses* is carried on in some places in so systematical a manner, as to combine the profit arising from the advance in the age of the animal, with that of a moderate degree of labour before they are fit for the services to which they are ultimately destined. In the midland counties, the breeders sell these while yearlings, or perhaps, when foals, namely at six or eighteen months old, but most generally the latter. They are usually brought up by the graziers of Leicestershire, and the other grazing parts of the midland counties, where they are grown among the grazing stock until the autumn following. At two years and a half old they are bought up by the arable farmers, or dealers of Buckinghamshire, Berkshire, Wiltshire, and other western counties, when they are broken into harness, and worked till they are five, or more generally six years old. At this age the dealers buy them up again to be sent to London, where they are finally purchased for drays, carts, waggons, coaches, the army, or any other purpose for which they are found fit. (*Marshall's Economy of the Midland Counties*, vol. i. p. 31.)

655. *In the west of Scotland, a similar mode of transferring horses from hand to hand is common. The farmers of Ayrshire, and the counties adjacent, who generally grow corn on not more than one fourth or at the most, one third of their arable land, and occupy the remainder with a dairy stock purchase young horses at the fair of Lanark and Camwath before mentioned; work them at the harrows in the following spring when below two years old, put them to the plough next winter at the age of two and a half, and continue to work them gently till they are five years old, when they are sold again at the Rutherglen and Glasgow markets at a great advance of price, to dealers and farmers from the south-eastern counties. A considerable number of horses, however, are now bred in the Lothians, Berwickshire, and Northumberland, the very high prices of late having rendered it profitable to breed them, even upon good arable ground; but many farmers of these counties, instead of breeding, still prefer purchasing two and a half or three and a half year old colts, at the markets in the west country or at Newcastle fair, in October; they buy in a certain number yearly and sell an equal number of their work horses before they are so old as to lose much of their value. (General Report of Scotland, vol. iii. p. 162.)*

## BOOK XII Training of Horses.

656. *Horses are trained for various purposes*, but principally for carrying our persons or drawing our burdens. Formerly burdens were principally borne on the back by pack-horses, but the improvements in our roads have removed them from the back, to machines called carriages, drawn by means of harness applied over the person of the horse. Under saddle we train horses at racers, hunters, hackneys, or troop horses. In harness we use them in coaches, stages, chariots and various lighter vehicles, or we employ them in waggons, carts, ploughs, and various other agricultural or commercial machines. Horses are held in obedience by means of bridle, with appendages called reins, which are long or short, as used in riding or driving. Horses are directed and urged forward by whip, spur and language, and they are chastised by the same means.

657. *The direction language used to horses* ought to be every where the same, which is the more easily accomplished, as words or phrases are sufficient for giving every requisite direction to a horse. The first of these words may be "on," or go on, or merely the common chuck of the tongue, &c. as used by all coachmen in the world; the second to make the horse go to the right-hand side, "right-hand," the third, to the left-hand side, "left-hand," the fourth to make them stop, may be "stop," or "stand-still." Any attempt to modify these directions might be given in the correct language of the country and not in provincial words, as go on, slowly briskly right-hand, a little round, or turn, left-hand, a little, or left-hand and round, stop, or stand gently &c. As a proof that only four words are requisite for giving every requisite direction to horses, we may mention that foreigners in Stockholm, Petersburg and Moscow who know nothing of the language, require only four corresponding words of Swedish or Russian to direct the native coachmen and stage drivers to any street, house, or place, the situation of which they know by the maps, or otherwise.

658. *The three natural and ordinary movements of horses* are, walking, trotting, and galloping, to which some horses naturally add another, which is known by the name of "ambling," or "padding." The trot is, perhaps, the most natural motion of a horse, but the pace, and even the gallop, are most easy to the rider.

659. *In breaking saddle horses*, the first thing is to make them familiar with man, and other general objects, and which is best effected at the earliest period, which then saves almost all the trouble of breaking, and readily follows as a matter of course: to effect this, the greatest kindness should be used to the colts from the moment they are dropped; they should be accustomed to be handled, should be fed with bread, put in various parts of the body, have light matters put on their heads and backs, and subjects of different colours and forms should be shown them with caution. While at foot, the mare and foal should be led out into roads, and where carriages pass, during which time nothing should be allowed to intimidate the foal. By this management, the animal will be easily prepared for the future operations and it is then that the single and the ploughed-hand farmer breeds, and which daily follows the mother in her work, as it were teaches itself.

660. *Breaking is* the next operation, and if the colt has been judiciously used, and taught familiarity and docility by early handling and kindness, it is by no means difficult. It should be commenced before the colt is two and a half or three years old. The first breaking of a horse is a thing of great consequence, as his value afterwards very much depends on it. The application of the saddle should be gradually done, and without alarm to the horse. After a colt has become habituated to the saddle and bridle, and has been exercised some time, morning and evening in dress, and become somewhat obedient, it is nearly

recommended that he be taken to some ploughed land, where he is to be walked and trotted until he be slightly fatigued. If the colt be very high spirited or refractory, or if he be not inclined to lift up his legs sufficiently it may be advisable to practise him on some very light-ploughed lands; but if otherwise, it is better to depress with this, and a hind end a road alternately used will, in general cases, be found preferable. It would be well that this preliminary practice should be performed in a cavernous to ensure obedience. When he is perfectly tractable during his exercise let a person used to him lay himself gently and by degrees across his back; and if he seem not to be alarmed, let him proceed at a foot-pace with his burden. When this occasion no alarm, let one leg gradually be aid over his back, the person at his head engaging his attention during the time, and encouraging him. The rider may then gradually raise himself up. The next step will be to mount him at once in the usual way, still having a judicious attendant at his head. This must likewise by no means be done suddenly, or at a jerk, but very gradually and slowly by several ridings and heavings. If he bear this patiently the person is to seat himself firmly on his back; but if he be troublesome and not tame enough, the person is to forbear the attempt to mount, and he is to be treated in the hand over the same ploughed lands or other ground again, till he is more fatigued, and willing to receive the rider quietly on his back. When this is done, the person who is on his back must encourage him, and the man who has his head must lead him a few paces forward; all the while encouraging him. The feet are to be fitted well in the stirrups, and the toes turned out; afterwards the rider is to shrink and move himself in the saddle, and the person who holds his head is to withdraw his hand a little further from the mouth. As the rider moves his toes forward, the holder must move him forward with the reins, till he is made to apprehend the rider's motion of body and foot, which must always go together, and with spirit, and will go forward without the other's assistance, and stay upon the restraint of the rider's hands. When this is accomplished, let him be cherished, and again have grass and bread to eat; and then let the rider mount and alight several times, encouraging him between each time, and thus he is to be managed till he will go on, or stand still at pleasure. This being done, the long reins may be laid aside, and the hand about the neck, which are always used on this occasion, and nothing will be necessary but the bridle and reins, with the saddle. A groom must lead the way before; or none in the horse going only straight forwards, and making him stand still when desired. In this manner, by some times following, and sometimes going before another horse on the trot, the creature will by degrees be brought to know that it is his business to be quiet and governable.

605. To teach a horse the different movements of walking, trotting, galloping and cantering comes next in order.

605. Walking is the slowest and least raised of all a horse's movements. It is performed, as any one may observe, by the horse's lifting up its two legs on a side, the one after the other, beginning with the hind leg first. Thus, if he leads with the legs of the right side, then the first foot he lifts is the far hind foot, and in the time he is setting it down (which in a step is always short of the bread of his fore foot on the same side) he lifts his far fore foot, and sets it down before his near fore foot. Again, just as he is setting down his far fore foot, he lifts up his near hind foot, and sets it down again just short of his near fore foot; and just as he is setting it down, he lifts his near fore foot, and sets it down beyond his far fore foot. This is the true motion of a horse's legs in a walk; and this is the pace in which many things are best taught, for instance when the horse is to be taught to turn to the right and left, or from one hand to another he is first to be taught it on the walk, then on the trot, and finally on the gallop. The walk is a pace to which teams, carriages, and road horses should constantly be well broke as being of great use in all such cases and intentions. It is an excellent pace too in a saddle horse, when well performed by being properly taught.

606. In trotting, the limbs are diagonally employed, but their times or times of rising and falling, are very different, as it is conducted slow or fast. In the slow trot the diagonal legs are elevated and replaced simultaneously while those on the ground are preparing to elevate themselves and the horse is for a moment on tiptoe but until the original diagonal legs are set down these are not wholly elevated there. As the horse is during the moderate trot at no time without support. But it is very different when the trot is accelerated, as to nine or ten miles an hour for then there is a period in every spring made by the diagonal members, when all the feet are in the air at the same time; and the body completely suspended from the ground by these means. Thus during this accelerated action, the off fore leg and near hind leg having been elevated in the air before they meet the ground, the near fore leg and the off hind one are not only prepared, as in the slow trot, to elevate themselves, but actually do so before the others are set down, consequently the feet, at this precise time, must be all in air. (See 846.) To speed in the trot, it is necessary that a horse pick up his feet quick, and extend them far forward. To the safety also, it is necessary he elevate his knees particularly at the same time the general

elevation of the whole limb is operated by high withers and oblique shoulders.

607. Three qualities are essentially necessary to make the trot useful. It ought to be extended, supple, and even or equal. These three qualities mutually depend upon each other so that you cannot pass to the supple trot without having first worked upon the extended trot and you can never arrive at the even and equal trot without having practiced the supple. The extended trot (see 846) is that in which the horse trots out without retaining himself going directly forwards; and this consequently is the kind of trot with which you must begin. The supple trot is that in which the horse, at every motion he makes, bends and plays his joints by the elasticity of the organs composing them which no colts or raw horses can execute, who have not had their limbs suppled by exercise. The even or equal trot is that in which the horse moves so equally and exactly, that his legs never cover more ground one than the other nor set one time more than another. To go from the extended trot to the supple, you must gently and by degrees lead to your horse; and when by exercise he has attained sufficient ease and suppleness to manage his limbs readily, you must incessantly hold him in still more and more, and by degrees you will lead him to the equal trot.

608. The manner of trotting a colt who has never been broken is as follows. — Put a plain saddle in his mouth, fit a girth to his nose, to the ring of which tie a longe of a reasonable length. Let a groom hold this longe, who having got at some distance from the colt, must stand still in the middle of the circle which the horse will make. Let another follow him with a long whip or chambrière in his hand. The colt being alarmed, will be forced to go forward, and to turn within the length of the longe, the groom must hold it tight in his hand; by this means he will draw so, or towards the centre, the head of the colt, and his scarce will of consequence be without the circle. In working a young horse after this manner do not press or hurry him. Let him walk first, and afterwards put him to the trot. If you neglect this method, his legs will be embarrassed; he will lean on one side, and be more upon one haunch than the other; the inner fore foot will strike against the outer one, and the pain which this will occasion will drive him to seek some means of defence and make him disobedient. If he refuses to trot, the person who leads

the shoulder will advance him by trotting him, or striking the ground with it. If he refuses to gallop instead of trotting, the ground must shake or jerk the card that is tied to the harness, and he will fall into his trot. (*Brevier's Art of Horsemanship*, vol. I. chap. 4.) The value of this lagging in a stride is incalculable, inasmuch as it supplies the shoulders, and gives them a greater extent of action. It also increases the action of the whole hind downwards, and accustoms the horse to effect other movements, to be performed with an elevated hand.

6953. The gallop is the swiftest natural pace of a horse, in which the two fore feet become elevated almost at the same moment, but one slightly takes the lead of the other, and must therefore be set down beyond and somewhat after it. Previous to this, however the hinder legs have become elevated with also a little precedence in the leg of that side which has been led by the fore. Such is the natural gallop of the horse when it is performed with its utmost velocity the limbs are simultaneous and synchronous. (6954.) In galloping the horse may lead with which fore leg he pleases; the most usual way is that with the right, in which case the gallop is said to be *just*; but whichever it is, the hind leg of the same side must follow it next, which forms an even or equal gallop, otherwise the legs are said to be disunited and the gallop to be *false*; to remedy which disorder the rider must stay the horse a little on the hand, and help him on the spur on the contrary side to that on which he is disunited. However, this rule has not been always strictly observed. For hunting horses have been trained to lead indifferently with both legs, because it has been found, that a horse which has never been suffered to gallop but with his right fore leg, has been worn out on one side, when he has been fresh and sound on the other. In order to make a stop in a gallop straight forwards, the rider should carefully put his horse together, without altering or disturbing the appui, and throw his body back a little to accompany the action, and to relieve the horse's shoulders. In doing this he should seize the time of making the stop, keeping the hand and body quiet still, exactly when he feels that he has put his fore feet to the ground, in order that by raising them immediately by the next motion which he makes, he may be upon his haunches. When horses do not answer to the lessons in the gallop, they should be galloped brinkly and then slowly again by turns, and they will thus be compelled to obey the hand and heel. In the slow gallop, as well as in the trot, it is sometimes necessary to close the heels to the horse's sides, which is called *packing*; but this should be done in such a manner as not to make the horse abandon himself upon the hand, and care must be taken that he be upon his haunches, and not upon his shoulders; and therefore, when packing, he should be kept in the hand. To put a horse well together and make him bring his hinder legs under him, the rider must close his legs upon him, putting them very much back: this will oblige him to slide his legs under him at the same instant let the hand be raised a little to support him before, and yielding again immediately. Let him be thus supported, and have the rein again from time to time, till he begins to play and bend his haunches, and gallop leaping and sloping down, as it were, upon them. Let the rider then press him with the calves of his legs, and he will thus become quick and sensible to the touch. If a horse has too fine a mouth, gallop him upon sloping ground: this will oblige him to lean a little upon the hand, in order the better to put himself upon his haunches, and through fear of hurting his bars, he will be prevented from resisting the operation of the bit. If the horse is heavy in hand, gallop him up sloping ground: and when his appui is too strong, this will lighten him. The gallop serves to assure and make steady a weak and delicate mouth, and also to surer a horse, and make him steady and active in his limbs. (*Brevier's History and Art of Horsemanship*, vol. II. p. 104. &c.) In galloping in a circle, the horse is continued always to lead with his fore leg within the turn; otherwise he is said to gallop *false*.

6954. The varieties of gallop may be reduced to the gallop of speed, the ordinary or *hand* gallop, and the canter: all others are but compounds of these. The gallop of full speed is the most simple of all the paces, being nothing more than a succession of leaps; but it requires repeated efforts to acquire its full speed: the fore parts being first raised and thrown forwards are followed by the hinder immediately; as the velocity increases, the fore and the hind legs become opposed to the ground at almost the same instant, thus forming a repetition of leaps. The ordinary or *hand* gallop does not differ from the gallop (6955.), except that the leading leg being elevated still earlier and being carried still more forward, is followed also by an earlier and a more considerable displacement of its fellow leg behind, which of course retards the velocity considerably and lessens the exertion. The school gallop is formed of this, with the haunches drawn more under and the fore hand more thrown up.

6955. The canter is different from the gallop in some essential particulars. Whether the gallop be fast or slow still the legs are at one period wholly removed from the ground, and the horse is all in air. In the canter on the contrary at no period is the horse completely elevated from the ground, but has always one or more points of contact with it. Blaine describes its operation thus:—When performed on the right, the horse commences by first placing his off hind leg a little beyond the other at nearly the same instant he elevates the fore hand, and places first the near fore leg on the ground the off doubling over and beyond, is placed in an instant after it. In the next movement the hind legs are thrown in and, while elevated, the off fore leg becomes raised from the ground: but the near fore leg is not elevated until the hinder ones are replaced. The near fore leg is, therefore, the whole point of support in cantering at such remove, and thus it is that cantering horses always first fall on that leg.

6956. The amble is a peculiar kind of pace, by which the horse changes sides at each remove: two legs of a side being always in the air and two on the ground. An amble is usually the first natural pace of young colts, which, as soon as they have strength enough to trot, they quit. There is no such thing as an amble in the modern manège; the riding-masters allowing of no other paces besides walk, trot, and gallop; their reason is, that a horse may be put from a trot to a gallop, without stopping him: but not from an amble to a gallop without stopping.

6957. The driving of cavalry horses is exclusively performed in the military establishments, and therefore can never be required of the farmer or breeder.

6958. The training of coach horses commences with taming, walking, trotting, and repeated lunging; and next with yoking and driving in a break or four wheeled frame, with no other load than that of the coach box or seat: placed in the usual position, the driver and his assistant sitting on a board fixed to the coach or hind axle, in order to be ready at a moment's notice to descend and restrain or direct the horses. Coach horses, from fifteen to sixteen hands high, should walk eight five miles an hour and trot twelve. They should be first accustomed to this exercise in the country next in the outskirts of a large city and lastly in the most crowded streets.

6959. The age at which a horse is fit to be worked in a coach is four and a half or five years; but by the fraudulent practice both of the country and town dealers, horses of three and four years old are frequently employed. The first business of the Yorkshire dealer who has three or four years old colts to dispose of, is to draw their owner teeth, in order to make them have the mouths of those of five. The sale undergoes the operation of docking and nicking; and after having been kept two or three months on mashes, rice of beans, ground oats, or boiled corn, they are sold to the London dealers, who, it is said, sell three three or four years old horses as if they were five years old. They are then taken into immediate work, either for the coach or saddle and in a few months are completely destroyed by this premature and too severe labour. The drawing of the teeth is not a fraud practised on the London dealers; they know the deception, and suffer even its delay done by the country dealers. It is requisite to be done some months before the London dealers finally sell them for use, or the teeth which denote a horse to be five years old would not be grown, consequently the deception could not have taken place.

6970. The drawing of cart and plough horses commences with taming before they are a year old, with walking and rubbing them down in the stable when they are two, and with training to work when they are of three years' growth. They should be placed under the charge of a very steady careful servant, who

will teach them to hack, and to go into the shafts. They ought not, however, to be made to draw any other than a very light empty cart till their fourth or fifth year; nor ought they to be put into the shafts of a thrashing machine before their fifth year. The first work to which an agricultural horse may be applied is harrowing; but this during the fourth year only half a day at a time, or with a light harrow the whole day. Next he may be put to plough with similar care and caution in regard to strength. In general, agricultural horses require very little training. Just one thing is too often neglected, and that is, teaching plough horses a quick stop, and keeping them at that stop ever after in working them. By not attending to this, and leaving the stop to be regulated by lazy spiritless ploughmen, the loss to many farmers is very considerable.

### BOOK XIII. The Art of Horsemanship.

6571. *Horsemanship, as an art is unquestionably of very ancient date, and it is curious how very different are the modes by which it is practised in different countries*—but which differences are yet principally confined to the situation of the legs of the rider—for wherever the horse is used to carry the person, it is by the rider placing himself astride the animal. Horses were used in this way for centuries before any apparatus was used or applied to their bodies to spare fatigue to the rider; and we know that the first saddles were mere pads strapped round the body, but without the appendages of stirrups. In England, riding is systematically divided into two kinds, which are *manège* and *hackney riding*.

6572. *Manège riding*, called also *riding the great horse*, in the strict application of the term, was formerly more practised than at present; and required a system of education for both horse and rider long and severe. Horses perfectly broke for the manège were formerly taught several paces and motions, as ambling, cantering, manegeing, yielding, canterole, and canter. The practice of these artificial cadences, it is supposed, injures the natural pace of the horse—and this circumstance, united to a particular form of horse (defective for other purposes) being required for the elasticity of these actions, has tended to bring manège riding as formerly practised, into disrepute. Manège riding also taught the constant application of the seat of the body of the rider to the seat of the saddle, during all the motions of the horse, and as a severe education, and a particular form, had bestowed ease and elasticity to the rudeness of the manège horse, the inconveniences of this seat were not felt. But when another form of horse, capable of great speed over excellent roads, was in general use, this kind of riding was found hurtful to both horse and rider; destroying the one, and injuring the other.

6573. *The art of proper riding as practised among experienced horsemen, is derived from a knowledge of the judicious application of the aids of the bridle as taught in our schools, and as practised in the army generally—and also from a proper application or placing the body on the horse.* These we certainly owe to manège riding; and a knowledge of them is as essential to the safety of the rider as it is to the grace of his appearance as a horseman. The proper art of riding embraces all that is taught in the best schools, or practised on the road, and is equally applicable to both. This is allowed to its fullest extent by those who have possessed themselves of the requisite information and practice on the subject; but is denied by those who, wedded to field riding, contend that the perfection of horsemanship consists in a simple bridle and a jockey seat.

6574. *The use of the curb bridle is considered in the schools to be essential to good riding*—by it the horse is not only restrained, but he is also aided and assisted. He is alternately thrown on his haunches, or forced on his forehead, by which changes fatigue is prevented to both. Great nicety however is required in the use of the curb, and without an inclination and ability to use it lightly and dexterously, a snaffle is the best and safest bridle. The curb is to be operated by a gentle turn of the wrist only; and the action of the hand in this respect should be as fine and as pliable as the fishing rod and line. The force of the curb should in every instance be proportioned to the mouth of the horse.

6575. *The best form of saddle for general riding is one in which the cantle is not so high as the military one so low as the racing saddle.* The pommel should be so more raised than is necessary to keep the whole completely free from the withers. The stirrups should be substantial, not only to prevent breaking, but also that by their weight they may fall to the foot when accidentally slipped away, which is of more consequence than at first sight may appear. If they are of the spring kind, it is also desirable—but it is still more so, that the spring stirrup leather should be used which prevents the danger arising from horses catching the leather in the projections of doors, gates, &c. Having saddled and bridled our horse, we will proceed to mount our rider.

6576. *If you would mount with ease and safety* says Hughes, stand rather before the stirrup than behind it, then, with the left hand, take the bridle short, and the reins together, help yourself into the stirrup, with your right, so that, in mounting, your toe do not touch the horse. Your foot being in the stirrup raise yourself till you face the side of the horse, and look directly across the saddle; then, with your right hand, lay hold of the hinder part of the saddle, and, with your left, lift yourself into it. When mounted, let your position on the saddle be square, and the purchase of your bridle such as not to pull your shoulders—and let your body be in

sub an even posture as if you held a rein in each hand. In holding the bridle, grasp the reins with your hand which should be held perpendicular with the reins passed, the lower within the hand, and the upper between the fore and next fingers (Fig. 847). The reins are then brought over the fore finger and firmly held by the thumb. It is often directed to place the little finger between the lower reins—the practice of this may be optional with the rider, and in a very fine hand is desirable. The bridle should be held at such a length as to enable you if your horse stumbles, to raise his head and support it with your arms; and by throwing your body backwards at the same time you frequently save a horse that would otherwise fall.

6577. *A graceful and proper seat on horseback is greatly dependent on a right disposition of the legs and thighs, which should hang nearly straight down, easily and without force or constraint*—all which is brought about by placing the body flat and evenly on the saddle and opening the knees, whereby the fork will come lower on the saddle. (Fig. 848.) The thighs should be applied to the saddle and to the sides of the horse by their inner surfaces so as to bring in the knees and toes; and although the line may be properly broken by some little irregularities, yet the feet, the knee, the hip, and shoulder, should deviate but little from one perpendicular line. The ball of the foot should rest within the stirrup, and should be even with the heel, or very slightly elevated above it. Avoid any stiffness in the legs, thighs, or body; all should be lax but in a state to be able to embrace the horse, either for support, or to side to him. The reins, particularly should be lax and pliable, as a coachman's on his box, and for the same reason; for by sitting thus loosely the rough motions of both are broken. To depend on the embrace of the knees for support is to lose the benefit of a true equipture of body, and is rather to stick on a horse than to sit on one.

6578. *When you are troubled with a horse that is vicious, which stops short, or by riding or kicking, endeavours to throw you off, you must not bend your body forward as is commonly practised in such cases; because that motion throws the weight backward, and moves you from your fork, or twists and casts you out of your seat—but the right way to keep your seat, or to*

recover it when lost, is to advance the lower part of your body, and to bend back your shoulders and upper part. In rising or standing alone, a horseman's best security is the bending back of the body. The rising of the horse does not affect the rider's seat; he is chiefly to guard against the fall of the animal's hind legs, which is best done by inclining the body backward. But the usual method of rising the knee is all sorts of danger only serves, in great shocks, to assist the violence of the fall. To save yourself from being hurt, in these cases, you must yield a little to the horse's motion; by which means you will recover your seat, if displaced, or keep it at such times as would dismount an unskilful horseman.

607a. If your lower gross severely, take the reins separately one in each hand, put your arms forward, and hold him short, but do not pull hard with your arms low. For, by lowering his head, he has the more liberty to throw out his head; but if you raise his head as high as you can, this will prevent him from rising behind. It is not reasonable to imagine, that, if a horse is forced towards a carriage which he has started at, he will think he is obliged to attack or run against it. Can it be imagined that the rider's spurring him on, with his face directly to it, he should understand as a sign to pass it? These rational queries are submitted to the serious consideration of such as are fond of always obliging their horses to launch these debates at which they are, or effort to be, frightened.

608. Indifferent horsemen, Lawrence observes, should never venture on horseback without spurs. Those who reflect upon the predicament of being placed between a deep ditch and a carriage, at which their horse shies, will see the necessity of this precaution.

609. Presumably in ascending every person will find his ascent to examining the state of both horse and furniture with his own eyes and hands; for, however good and careful his groom may generally be, it is a maxim, that too much ought not to be trusted from the head of him who labours with his hands. Besides, all such sedulously avoid trouble, particularly in nice matters. For example, see that your curb is right; that your reins are not twisted; that your girths, one over the other, do not bear exactly alike; that the pail be not wrinkled up; but, above all, that your saddle lies exactly level upon the horse's back.

610. On getting on the horse's back hold the bridle and mane in the same manner as when you mounted, hold the pommel of the saddle with your right hand; to raise yourself, bring your right leg over the horse's back, let your right hand hold the kind part of the saddle, and stand a moment on your stirrup, just as when you mounted. But beware that, in dismounting, you bend not your right knee, lest the horse should be touched by the spur.

611. The jockey mode of riding is practiced in its fullest extent in racing. With some modifications it is also in use by many who esteem themselves excellent fox-hunters. With still greater modification it is by its advocates practiced also on the road. English post-boys unite these two kinds of riding in a manner at once easy to themselves and horses. True jockey riding consists in the use of a snaffle bridle, which is held firmly, not as an advocate for it expresses himself to enable the rider to give his horse the proper pull. To this end the same writer recommends a firm seat up, right, and as you would sit in a chair with the knees nearly as much bent, and turned inward; the toes somewhat out and upward; the leg falling nearly straight, and the foot home in the stirrup (fig. 549) elbows close to the sides; hands rather above the horse's withers, or pommel of the saddle; and the view directed between his ears. The same writer further advocates the jockey mode, by commenting on the decline of riding-houses frame, and the universal preference given to expedition, which he says, fully confirm the superior use and propriety of a jockey-seat. Indeed, our riding-schools are now, he continues, considerably reformed from the stiffness of ancient practice in all respects. It was the custom formerly in the schools, and indeed pretty generally upon the road, to ride with the tip of the toe only in the stirrup; so if it were of more consequence to prepare for falling with safety, than to endeavour to sit securely. Those who preserve a partiality for this venerable custom, we would advise to suspend a final judgment, until they have made a few more essays upon a huge cool-halt half-breed, of that kind which cannot go, and yet won't stand still, and will dart from one side of the road to the other, so if he really desired to get rid of his burden. Nor is the ball of the foot a proper rest; chiefly because inconvenient to that event, or rather almost kneeling posture which is required in speedy riding. The riding-houses seat is preserved by the balance or equipoise of the body solely; that recommended here by the firm hold of the knee, which is obviously strengthened by the opposite directions of the knee and the one in, the other outward.

#### SECT. XIV Feeding of Horses.

624. The feeding of horses generally is an important feature in their management. In considering the food for horses, we are apt to locate our notions to the matters around us, without taking into account that every country has its peculiar products. White observes, that the best food for horses is hay and oats, and had he added for English horses, it might have been just, but without such notice the assertion is much too confined. "In some sterile countries, horses are forced to subsist on dried fish, and even vegetable mould in Arabia, on milk, flesh balls, eggs, broth &c. In India, horses are variously fed. The native grasses I judge very nutritious. Few perhaps use oats in India. Barley is not commonly given to horses; indeed, it is rarely grown. In Fertia, barley is a common food for good horses. In some parts of India (in the Malabar country) salt, pepper and other spices are made up into balls, as big as billiard balls, with flour and butter and thrust down the animal's throat. It is supposed to give them animation and fire; no doubt it promotes digestion. Meat broth (especially sheep's head) is also given to horses. English gentlemen sometimes steep these usages. Different kinds of grain are given to horses in different parts of India. In Bengal, a vetch, something like the tare, is used. On the western side of India, a sort of puggan pea, called gram (*Cicer aridum* L.), is the usual food with grass in the season, and hay all the year. Indian corn or rice is I think, seldom if ever given to horses in India as ordinary food. In the West Indies they are fed on molasses, Guinea corn, and sugar cane tops; and, in some instances, on the sugar itself, in the form of molasses. In France, Spain, and Italy, besides the grasses, the leaves of flax, vetch, the tops of acorns, the seeds of the carob tree, &c. are used."

625. The food of British horses may be divided into herbage, grain, roots, and mixtures. Of herbage, the principal kind is the purple grasses, when either mowed or dried into hay. Wheat often mows in their natural state, and is called green hay; but when these matters are cut, and carried into the stable to a horse, he is said to be mowed. Hay is herbage cut during its flowering and seeding process; which being subjected to the action of the sun and air a proper time, are then collected into large masses called ricks, where a certain degree of fermentation takes place before the matter is fitted to become wholesome or nutritious, or before it receives such alteration as fits it for sustaining further decomposition and decay. The fermentative movement of this fermentation process forms one of the greatest dangers in hay-making. Pursued to a proper extent, the remaining moisture acting on the acidulous parts, as the seeds, &c. in conjunction with the heat evolved during the process, as it were melts the whole, and sugar is produced. Pushed beyond this, the hay becomes carbonized, and now-burnt; its nutritive properties are lessened, and its noxious qualities increased, it being found in this state to excite colic, vomiting, and extreme weakness and constipation. 626. The quality of the hay is too little attended to, but which is of very great importance; and more particularly so where little corn but much hay is given. Hay should be matured in the best, whether shadowy, clover, or mixed. Many horses thrive best on clover hay, particularly draught horses. It is very grateful to horses, and it serves much more of service; to sprinkle hay with water has the same effect, but it should only be done as it is wanted.

6954. Hay should never be given in large quantities at a time; horses breathe on it, become disgusted, and then waste it. They also, when it is given, eat too much and distend their stomachs, and then become sick. Hay should not be kept in the stable in great quantities, otherwise it becomes impregnated with the volatile effluvia of the stable, and is then spoiled. As substitutes for hay the straw of wheat, barley, oats, and rye are used; but these are much less nutritive and rather serve to excite mastication by mixing them with other matters, than to be depended on for animalization. On hay when good, many horses subsist; and when no exertions are required of them they are sufficiently nourished by it.

6957. The grain used as horse food is of various kinds, possessing, it is supposed, different degrees of nutriment, according to their different proportions of gluten, sugar, or farinaceous matter. In South Britain, oats are almost exclusively used as horse grain, and which according to the experiments of Sir Humphry Davy, as we have seen (§ 8000.) contain 745 parts of nutritious matter out of 1000. In wheat, 955 parts of 1000 are nutritious; but wheat is seldom given with us except to racers and hunters, or on extraordinary occasions when great excitement is required; when it is sometimes given in the form of bread. Barley is more frequently given than wheat, and contains 920 parts in 1000 of nutritious particles. Made into malt, where its sugar is evolved, it becomes still more highly nutritious. Barley appears to have been the principal horse food of the ancients.

6958. The pulsed used as horse food, are the seeds of beans, peas, vetches, &c. Beans are seldom given alone on account of their heating and astringent qualities, but are mixed with straw or hay cut into chaff, either whole or broken.

6959. The roots used as horse food are such as contain much sugar but in which the gluten is in small proportion only. Carrots stand deservedly high on this list. They are favourable to condition, as the skin and hair always look well under their use. They are highly nutritious we know, from the fattening that occurs from them. They also generate good flesh, as we know horses can work on them, and have their wind increased by their use. Indeed, so favourable are they to the proper action of the lungs, that a course of carrots will frequently remove the most obstinate cough. The parsnip has similar properties. Swedish turnips, as having the saccharine particles in abundance, are also found good. Beet-root likewise.

6960. *Mistakes, or mixed food*, is formed of several kinds among agriculturists; and it possesses many advantages, as it can be varied to every taste, and made either cooling as an alternative, or nutritious and stimulating as a tonic. Although it is principally used for waggon, post, and farm horses, it would be better were its use more universal. Of this manger feeding, one of the best is formed from a chaff made of one part best meadow or clover hay and two parts wheaten straw to three bushels of this mixture add one of bruised oats. The importance of bruising or flattening the oats is very great. When used whole, the grains are apt to slip between the teeth or the chaff in mastication. In fact, corn when either given alone, or with chaff, would, in most instances, benefit by bruising. To horses under great exertion the stomach must be, to a certain degree, weakened also; in such cases, by bruising their corn not only the work of mastication is much of it spared, but that of the stomach also. In old horses with worn teeth, bruised oats are of great consequence. Fast-eating horses do not properly masticate more than one half of their corn, much of it remains in the dung so perfectly unaltered that it will afterwards vegetate, and an experienced agriculturist states, that during his residence in India, in a season of scarcity, half-starved wretches actually followed the cavalry and drew their principal subsistence from the unaltered grains of corn extracted from the excrement of the horses. Of this manger food, three, four, five, or six pecks may be given daily according to size and exertions required, and as but little hay is required, so hard-worked horses are enabled to lie down much more, instead of standing on their already fatigued limbs to eat hay.

6961. Cooked food is also now much used by practical agriculturists for horses. The articles made use of are potatoes, carrots, turnips, or parsneps. To horses with their digestion weakened by hard work, old age, or other causes, food in sufficient quantities, thus already reduced to a pulsatious mass, resembling chyme, without the loss of time, or the waste of saliva, may be very important. For as Curwen very judiciously observes, a horse will consume nearly six hours in eating a skin of hay whereas he will eat a stone of steamed potatoes in twenty minutes. Horses are observed of themselves to lie down after eating cooked food sooner than other times.

6962. The quantity of food to be given to a horse must be regulated by circumstances, the principle of which is the exertions or nature of the work required of him. If this be simply laborious, as driving at loads, or carrying of weights, all that is requisite is that the food be sufficiently nutritious. The bulk from whence such nutriment is gained is not a matter of import; but if such exertions are to be combined with celerity as in our racers, hunters, &c., it is evident that such feeding is best adapted to the end required which combines nutriment without bulk; and which increases the durability by increasing the mental irritability and thus giving tone and courage. These are found to be better derived from a proportionate allowance of grain or corn, than any other mode of feeding at present known. It remains only to add, that although experience has fully proved this, in all cases where the exertions are extreme, yet it has also led to another evil, by introducing a plan of treating all horses of value alike. Thus, most of the more valuable hackneys, the carriage horses of the wealthy &c. are accustomed to be fed, not as though their exertions were moderate, but as though they were unceasing, to the destruction of a vast quantity of valuable corn. From thousands of such horses, at least one third of their hay and corn might be advantageously abstracted.

6963. The great quantity of food injures not only the community but the horse also. The stomach becomes distended by over-feeding and it then becomes weak and incapable of a healthy digestion; crickets, hiccups, and purgatives follow or when the stomach does digest this undue quantity it generates fulness, which shows itself in inflammations or stultness, appearing in the form of cracks and grunts.

6964. A horse in full work, of whatever kind, will require, according to his size a peck of sound oats in twenty-four hours; and when the work is unrelenting, as in post, stage-waggon, or other very large and hard-working horses, even more may be required. Some post horses have an unlimited quantity given them; but this practice is always erroneous. If they eat more, it serves only to distend the stomach unduly and also to require stronger digestive powers. If they leave on it they waste it, and it is wasted, or a more greedy one swallows it up without mastication; and both stomach, horse, and master are thereby robbed. It is of consequence that the oats, as an important part of horse food, should be perfectly sweet, free from must, and not ill-dried. The skin should be thin, but the grain plump and heavy, yielding from thirty-eight to forty pounds the bushel. To encourage a slow and thorough mastication, sprinkle them with water and spread them well over the manger. The quantity of hay required for saddle horses which are corn-fed is from six to eight pounds in twenty-four hours. If the quantity of corn be small, and the horse large, ten or twelve pounds is not too much. This quantity is also sufficient for carriage or coach horses, as they usually have either corn or mixed food in sufficient plenty also. For waggon and the larger agricultural horses, from fifteen to twenty pounds may be requisite. When it can be conveniently done, the quantity of both hay and corn should be divided into four portions. The largest portion both of hay and corn should be given at night; the next in quantity in the morning; the other two portions at noon and about four in the afternoon. This, however, must depend on the work of the horse, and other circumstances.

6965. Watering of horses is an important part of their management, and many errors are committed relative to it. It is equally erroneous to deter them from it, as it is to allow them too much; and the former is much the most common evil. In summer, or when from great perspiration the animal feels

are wasted, it generates fever, and weakens the strength and spirit. All horses prefer cold water, and as nature is unerring, there is no doubt but that it is the most wholesome. As some horses drink quicker than others, it is best a good custom to take riding horses to a pond, unless at night, when the quantity cannot injure them; or when not intended for early work the next morning, as hunting, &c.

665A. The necessary quantity of water the a horse should be regulated by circumstances, as the weather, the work, &c. In common cases, a large horse requires rather more than the half of a large stable full full twice in the day. At night a full pail should be allowed. Horses should never be galloped after drinking; it has destroyed thousands, by gripes, inflammations, and broken wind. This custom also uses horses to expect they are to run away directly they are suddenly watered at any time. Others, expecting they are to be delighted with a gallop, will avoid drinking at all. The most that should ever be done, is to make no horse to drink his fill at a river or pond, but having given him half what is necessary walk him ten minutes, and then give him all that is required, and walk him again.

#### SECT. XV Stabling and Grooming of Horses.

667 The stabling of horses is likewise a most important point in their management, the more so as being wholly a deviation from nature—hence, under the most judicious management, it is liable to produce some departure from health; and as sometimes managed, is most hurtful to it. Clothing, dressing, or combing, and exercise, are also highly important.

668A. Heavy stables should be large, cool, and airy. It is too common to suppose that warmth is so beneficial to horses, that they cannot be kept too hot—but there is reason to suppose that many of the diseases of horses are attributable to the overrating effects of unnatural heat, and of an air breathed and re-breathed over again. Blaise says, it is not alike repugnant to reason and experience, to expect to keep animals in health, that from stables heated to sixty degrees, and further protected by warm clothing, are first stripped, and then at once exposed to a temperature at the freezing point? If it be argued that habit and exercise render them less hurtful it will be easy to answer that their original hardiness is lost by confinement and artificial treatment, and that neither does exercise always tend to obviate the effects of the sudden change. For our best carriage horses, and hackneys also, have often to walk hours in roads and streets the convenience of their owners, or the pleasure of the groom.

668B. The heat of a stable should be regulated by a thermometer and the heat shown by it should never exceed 50° of Fahrenheit in winter, or 60° or 65° in summer. To renew the air, the stable should be well ventilated, and which is best done by trunks or tubes passing from the ceiling through the roof.

670A. A stable should not only be well ventilated, but it should be light also—and the windows should be so constructed as to admit light and air without producing a current of wind on the bodies of the horses. Darkened stables are very hurtful to the eyes; neither do they as was formerly supposed at Newmarket, tend to the condition or rest of a horse.

670B. A stable should have a close ceiling to keep the dust and dirt from the hay-loft from entering the horse's eyes. It is also necessary to prevent the ammoniacal gases from ascending and lodging in the hay. It is preferable that the hay loft be altogether removed from over the stable and if a very high ceiling even to the roof were substituted, it would be for the benefit of the horses.

670C. The form of the rack and manger should be attended to. Sloping racks are disadvantageous, as encouraging dirt on the eyes. They should therefore be upright, and by no means so high as they usually are, by which the head and neck are put injuriously on the stretch. As a proof that this is unpleasant to horses, many of them will pull out all the hay and then leisurely eat it. The manger should be wide at the bottom, and of a proper height—care should be taken that no splinters are present to endanger the lips, nose, and mouth. The halter reins should, in good stables, be adhered to run within a groove within the manger post, to prevent the reins entangling the legs. It is become the practice in some stables appointed to post, stage-coaches, and other hard-worked horses, to abandon hay racks altogether, but the hay being placed on the ground before the horse encourages him to be down and eat it by which much rest is afforded to the weary limbs, and much improvement to the feet.

670D. The stalls of a stable should be wide. Strains in the back, and sometimes even worse evils, are the consequence of the standings being too narrow. Balls are objectionable from the ease with which horses can kick over them—and also from the quickest feeder getting most food, when several horses stand together behind.

670A. The solidity of the stable is a matter of much dispute: when too much raised, as in dealers' stables, they put the back strains on the stretch, and fatigue horses much. It is more natural that they should be even; or that a very slight slope only be allowed to carry off the urine. The best mode, how ever of carrying off the urine is by means of a small grating to each stall, communicating with a cess-pool without doors, which should be closed up, that a current of air may not come through the grating. Such a contrivance will effectually carry off the water and prevent the volatile alkali of the urine from impregnating the air around. For the same reasons, the dung should be removed, if possible, wholly without the stable as soon as dropped; for the exhalations from that are also ammoniacal, and consequently hurtful. To this cause alone we may attribute many diseases, particularly the great tendency stabled horses have to become affected in the eyes. The pungency of the effluvia is familiar to every one on entering a close stable in the morning, and when the long-soiled litter is removed, it is absolutely unbearable.

670E. The litter of horses should be kept dry and sweet, and should be often removed. When it is suffered to remain, under the notion of making better dung, the horse may be ruined—neither does the manure benefit as is supposed—for when it is removed to the dung pit, the close confinement does it more good than the open exposure in the stable, when it puts with its salt, on which its properties as manure partly depend.

670F. Horses should not stand on litter during the day although very generally suffered to do so. Litter is thought to save the shoes and even the feet, by preventing the uneven surface of the stable from hurting them—but it holds the urine; it injures the feet; and is very apt to encourage swelling at the heels: as we know by removing it, when they immediately subside. A little litter may be strewed behind to obviate the effect of kicking, or the spashing of urine in mares.

670G. The clothing of horses is apt to be carried to an erroneous extent as the heat of their stables. When horses go out in cold weather and are intended to have merely a long walking exercise then clothing is very proper—but it must be evident, that when taken clothed from a stable and exercised briskly as is so frequently practised, it is erroneous; for not only are the clothes wetted and thus liable to give cold, but the horse is unprepared to go out afterwards with a saddle only. Saddle horses kept in condition stand clothed in a jersey sheet, and girthed with a broad roller with occasionally the addition of a quarter piece; the breast plate is sometimes put on when going out to exercise; the head is used to race horses only, except in case of sickness. All horses, except mares, are best without clothing in the summer season; at the most a linen sheet only should be allowed to avoid the dust and flies.

670H. The grooming or dressing of horses is generally thus practised—Having tied up the horse's head, take a currycomb, and curry him all over his body, to raise the dandruff or acari, beginning first at his neck, holding the left cheek of the head-stall in your left hand, and curry him from the setting on of his head, all along his neck, to his shoulder, and so go all over his body to the buttocks, down to his hocks; then change your hands, and curry him before on his breast, and laying your right arm over his back, run your right side to his left, and curry him all under his belly to his chest, and so all over very well from his hocks and shoulders upwards. After that, go to the far side, and do in like manner. Then take a dead horse's tail, or a dressing-stick of cotton, and strike that dust away which the curry-comb has

raised. Then take a round brush, made of bristles, and dress him all over both head, body and legs, to the very fetlocks, always cleaning the brush from that dust which it gathers, by running it upon the curry-comb. After this, take a hair-cloth, and rub him again all over very hard, both to take away the loose hairs, and to help to lay his coat; then wash your hands in fair water, and rub him all over with wet hands as well head as body, for that will cleanse away all those hairs and dust the hair-cloth left. Lastly take a clean cloth and rub him all over till he be very dry; for that will make his coat smooth and clean. Then take another hair-cloth (for you should have two, one for his body and another for his legs) and rub all his legs exceedingly well, from the knees and hocks downwards to his very hoof picking and dressing them very carefully about the fetlocks from gravel and dust, which will be in the bending of his joints.

6709. *The curry-comb should not be too sharp, or, at least, not used in a rude and severe manner so as to be an object of torture and dread, instead of delight and gratification to the horse.* It is too often the fate of thin-skinned horses to suffer much from the brutality of heavy-handed and ignorant fellows, who do not recollect that the unhappy animal is suffering, every time he writhes and attempts to escape from the comb or brush, the same tortures that they themselves experience when tickled on the soles of their feet.

6710. *The care of the legs and feet forms a most important branch of stable discipline.* The legs must be kept perfectly dry and clean. Dirt suffered to form a lodgment, or wet remaining upon the legs in cold weather will fret the skin and cause cracked heels, greses, maffenders and splendens, rat's-tail, crowns, scabs, and such a train of stable plagues, as may baffle the most vigorous efforts during a whole winter. If any disposition to swellings, cracks, &c. make their appearances on the legs, particularly in winter, moderate bandaging which every good groom knows how to perform will contribute to remove the evil. If it, however, increase, have recourse to the veterinary directions. It forms a part of the constant attention of a good horse-keeper to see that the feet of his horses be well cleansed beneath the shoe with the picker from all small stones or gravel, at every return from abroad. The shoes must be examined that their ends do not press into the crust, and that the nails be fast, and that the clinches do not rise to cut the horse. In these cases, instant application must be made to the farrier: horses ought by no means to remain in old shoes until the toe is worn away or the webs become so thin that there is danger of their breaking inless in case of brittle hoofs, when it is an object to shoe as seldom as possible. Upon the average, good shoes will wear near a month. Sticking the toes is, in general, a useful practice, but less necessary when the best iron is made use of. Where any tendency to dry hoofs exists, the feet should be stopped with equal parts of clay, cow-dung and chamberlye every night, otherwise, twice or three times a week will be sufficient. A still better stopping is made by adding a little tar to the other matters. It is also prudent, when the hoofs have any tendency to hardness and contraction, to water the front part of the stall a little and also occasionally or constantly to hang around the hoofs an apparatus made by doubling a circle of woollen cloth over a tape, which should be tied around the fetlocks loosely: the two segments of the cloth will then fold around the hoof and correspond to it in shape. This may be dipped in water and will be found very convenient in keeping the feet moist and cool. Very brittle hoofs are greatly benefited by brushing them over with a mixture of whale oil and tar. It is considered as beneficial, in general, to take off the shoes of a horse who is accustomed to stand long in the stable, and who does no work, and to substitute tips: the growth of the crust and the enlargement of the heels being thereby promoted.

6711. *The care of the furniture and trappings is another part of the duty of a horse-keeper.* These are best kept in order by being instantly rubbed clean after use and placed in a dry situation; by which method, neither oil nor scouring-paper is often found necessary. Great care should be taken to dry the pads of the saddles after journey, and never to put a hard and damp saddle upon the horse's back. The same is also necessary with regard to the body-clothes. The pads of the saddles ought to be kept perfectly soft, and free from dirt and sweat and, after use should be dried either in the sun or by the fire, and hung in a dry place: the body clothes also should be washed much oftener than they generally are, and ever kept perfectly dry and in a sweet state.

6712. *The exercising of horses is essentially necessary for their health as it counteracts the effects of the artificial life we force on them.* High feeding, heated stables, and unnatural clothing are particularly the first, counteracted by proper exercise; and without it, horses become puny, fat, heavy and groined; for when the secretions do not find themselves natural vents by perspiration, &c., they will find themselves artificial ones. Exercise keeps down the fat, and it also hardens and condenses the muscles by drawing their fibres nearer together: it likewise enlarges the muscles. Thus the appearance, as well as the feel, when we handle the flesh of a horse in condition by proper exercise, is totally different from those of one merely full of flesh by fat, &c. Exercise increases the wind by taking up the useless fat, and by accustoming the lungs to expand themselves.

6713. *The quantity of exercise necessary for a horse must be regulated by a variety of circumstances as age, constitution, condition, and his ordinary work.* A young horse requires more exercise than an old one, but it should be neither very long, nor very fatiguing. Some colts are observed to come out of the breaker's hands with collets and warts, owing to the severe exercise they have undergone. When horses are in general work a little walking exercise in the morning in body-clothes, if the condition be very high, or the weather be very cold, is all that is necessary but, on days when their common work is not expected to occur, a full-fed horse should be exercised twice a day an hour at each time, or, if only once a day, then an hour and a half or two hours exercise should be given. Two thirds of which ought to be passed in walking; the other should be passed in a moderate trot in the hackney and divided into galloping and trotting in the hunter. The racer has his regular gallops at stated periods but the exercise of each should always finish with a walk of sufficient length, to bring the horse in cool, both in person and temper.

## BOOK XVI Management and Working of Horses.

6714. *The working of horses includes the racing, hunting and journeying of saddle horses; and the treatment in harness of coach, waggon, cart and farm horses.*

### SUMMARY 1 Management and Working of Race Horses.

6715. *In the managing and working of race horses three things are to be considered, the preparation of the horse, the conduct of the rider, and the after treatment of the horse.* The preparation of a race horse for running a race is not the work of a few days, if there be any great dependence on the success. A month at least is required to harden his muscles in training, by proper food and exercise, and to refine his wind, by clearing his body to that degree of perfection that is attainable by art. It is first necessary to ascertain correctly his present state of the horse, as whether he be low or high in flesh, and in either case a proper estimate should be formed of the time and means required to bring him into true running condition.

6716. *If a race horse be low in flesh, it is necessary to judge of the means of such state, and to act accordingly the necessary proceedings for which we detailed in treating of condition. (662.)* It is to be remarked, that colts are less to be depended on for this purpose than generous find, as stall makes, and if any thing of the kind be used, let it be the simple cordial ball. (*Vet. Pharm.* 658.) Feed frequently and by little at a time while he is thus low, let his exercise be walking only, and by no means spare his water: or he will become hide-bound: carefully watch him, that full feeding may not disengage

by teaching his heels over, or his neck uprightly; and if such appearances occur, much time, and much his own strength, otherwise obtain from physicians, until he is in better health. As he improves in condition, increase his exercise, but not to such a degree as to make him sweat. His feed must now be the best corn and beans, with wheaten or barley straw; the beans and oats are to be put into a bag, and beaten till the husks are all off, and then winnowed clean, and the bread, instead of being shipped in the common way, is to have the crust clean cut.

6715. If the horse be in great flesh and spirits when taken up for his month's preparation, cordials are altogether unnecessary, and the chief business will be to give him good food, and so much exercise as will keep him in wind, without overtaxing or fatiguing him. When he takes larger exercise afterwards, towards the end of the month, it will be proper to have some horses in the place to run against him. This will put him upon his mettle, and the beating them will give him spirits. This, however, is to be carefully observed, that he has not an influenza, or in the language of jockeys, a bloody heat given him for ten days or a fortnight before the place is to be run for; and that the best heat that is given him the day before the race must be in his clothes, this will make him run with greatly more vigour when stripped for the race, and feeling the cold wind on every part. In the second week, the horse should have the same food and more exercise, and in the last fortnight he must have dried oats, that have been hulled by beating, after this jockeys wet them with the whites of eggs, beaten up, and then laid out in the sun to dry, and when as dry as before, the horse is to have them. This sort of food being considered by them as very light of digestion, and very good for the creature's wind. The beans in this time should be given more sparingly, and the bread should be made of three parts wheat and one part beans, or of wheat and barley in equal parts. If he should become inactive under this course, he must then have bran-water to drink, or some ale and wheaten of eggs beaten together, and keep his body warm. In the last week all minding is to be omitted, and better water given him at its place, and every day till the day before the race, he should have the fill of hay, then he must have it given him more sparingly, that he may have time to digest it, and in the morning of the race-day, he must have a toast or two of white bread soaked in ale, and the same just before he is led out of the field. This is an excellent method, because the two extremes of fullness and fasting are at this time to be equally avoided. The one affecting his wind, and the other decreasing his heat, as he has had his food, the latter is to be shook up, and the stable kept quiet, that he may be disturbed by nothing till he is taken out to run.

6716. In the choice of a rider for winning a race, it is necessary as far as possible, to select one that is not only expert and able, but honest. He must have a very close seat, his knees being turned close to the saddle skirts, and held firmly there, and the toes turned inwards, so that the spurs may be turned outward to the horse's belly, his left hand governing the horse's mouth, and his right the whip. During the whole time of the race, he must take care to sit in the saddle, without swaying or standing up in the stirrups. Some jockeys fancy the last a becoming seat, but it is certain, that all motions of this kind do really enervate the horse. In spurring the horse, it is not to be done by sticking the calves of the legs close to the horse's sides, as if it were intended to press the wind out of his body, but, on the contrary, the toes are to be turned a little outward, that the heels being brought in, the spurs may just be brought to touch the sides. A sharp touch of this kind will be of more service toward the quickening of a horse's pace, and will excite less blood than one of the common coarse kind. The expert jockey will never spur his horse until there is great occasion, and then he will avoid striking him under the fore bowels between the shoulders, and the girth, this is the tenderest part of a horse, and a touch there is to be reserved for the greatest extremity.

6717. As to whispering the horse, it ought always to be done over the shoulder on the near side, except in very hard running, and on this point of victory, then the horse is to be struck on the flank with a strong jerk. For the skin is the most tender of all there, and most sensible of the lash. When a horse is whipped and spurred, and is at the top of his speed, if he clap his ears in his pole, or whack his tail it is a sign that the jockey treats him hard, and then he ought to give him as much comfort as he can by seating the saddle backwards and forwards in his mouth, and by that means forcing him to open his mouth, which will give him wind, and be of great service. If there be any high wind stirring in the time of making the third jockey will let his adversary lead, holding hard behind him till he sees an opportunity of giving a horse, yet, in this case, he must keep so close behind, that the other horse may keep the wind from him, and that he, sitting low may at once shelter himself under him, and assist the strength of the horse. If the wind happen to be in their back, the expert jockey is to keep directly behind the adversary, that he may have all the advantage of the wind to blow his horse along, as it were, and at the same time intercept it in regard to his adversary.

6718. When running on level smooth ground, the jockey is to beat his horse as much as the adversary will give him leave, because the horse is naturally more inclined to spend himself on this ground, on the contrary, on deep earth, he may have more liberty, as he will there spare himself.

6719. As riding up half the horse is always to be favoured, by bearing him hard, for fear of running him out of wind, but in running down hill, if the horse's feet and shoulders will bear it, and the rider dare venture his neck, he may have a full horse. If the horse have the heels of the rest, the jockey must always spare him a little, that he may have a reserve of strength to make a push at the last post.

6720. On the jockey's knowing the nature of the horse that is to run against him, a great deal depends for by managing accordingly, great advantages are to be obtained. Thus if the opposite horse is of a hot and fiery disposition, the jockey is either to run just behind him, or cheek by jowl with him making a noise with the whip, and by that means forcing him on faster than his rider would have him, and consequently spending him to much the sooner; or else keep him just before him in such a slow gallop, that he may either overreach, or by treading on the heels of the fore-horse, endanger tumbling over. Whatever be the ground that the adversary's horse runs worst on, the cunning jockey is to ride the most violently over, and by this means it will often happen, that in following he either scrambles or claps on the back answers. The several corrections of the hand, the whip, and the spur are also to be observed in the adversary, and in what manner he makes use of them, and when it is perceived by any of the symptoms of holding down the seat, or whacking the tail, or stretching out the nose like a pig, that the horse is almost blown, the jockey is to keep him on to this speed, and he will be soon thrown out or distanced. If the horse of the opposite looks dull, it is a sign his strength fails him, and if his flank heat much, it is a sign that his wind begins to fail him, and his strength will soon be at an end.

6721. The after-management of a horse who has run includes the treatment between the heats, and the treatment after the race is over. After every heat for a plate, there must be dry straw, and dry clothes, both clean and woollen, ready to rub him down all over after taking off the sweat with what is called a sweat-knife. That is, a piece of an old sword-blade, or some such thing. After the horse has been well rubbed, he should be washed all over with clean water till the time of starting again. When it is certainly known that the horse is good at the bottom, and will stick at the post, he should be rid every heat to the best of his performance, and the jockey is as much as possible to avoid riding at any particular horse, or staying for any, but to ride out the whole heat with the best speed he can. If, on the contrary, he has a dirty horse in state, and one that is hard to manage, hard-mouthed, and difficult to be held, he is to be started behind the run of the horses with all imaginable caution and gentleness, and when he begins to ride at some command, then the jockey is to put up to the other horses, and if they ride at their own, and are hard held, they are to be drawn on faster, and if it be perceived that their wind begins to rise hot, and they want a job, the business is to keep them up to that speed, and when they are all come within three quarters of a mile of the post, then is the time to push for it, and use the utmost speed in the creature's power.

6722. When the race is over the horse is immediately to be clothed up and rode home, and immediately

on his coming into the stable, the following drink is to be given him : — Beat up the yokes of three eggs, and put them into a pint and a half of sound ale, made warm and let it be given with a horn. After this he is to be rubbed well down and the saddle-place rubbed over with warm water and vinegar, and the places where the spurs have touched, with the same; after this he should have a feed of rye-bread, then a good meal, and at some time after these as much hay and oats as he will eat. His legs, after this, should be bathed some time with a mixture of vinegar and water.

### SUBJECT 2. *Management and Working of the Hunter.*

6755. The managing and working of the hunter includes his preparation for hunting, his condition and his treatment while taking his regular day's work in the field, whether after buck fox, or hare hounds.

6756. The preparation of the hunter must, like that of the race horse, be commenced by an estimate of his state and condition. If taken fresh from grass, it should be in due time first, that he may be well prepared, and next, because the grass does not yield much nutriment in the heat of summer. A still better method is to confine to let him run out in the day and graze, having a shed to house him from heat and rain. He is also to be fed and exercised, nearly as in the common training, for hunting condition. In this way he is sure to be free from cracks, hide-bound, or sorfeit, and he will prove infinitely more hardy afterwards. It is even the practice with some of the best sportsmen to allow their horses to run out all the hunting season unless the weather be very severe; when they are only stabled in a loose place. They are allowed as much corn as they can eat, and are found, if a little rougher in their coats, infinitely superior in hardihood, and exemption from the dangers of cold.

6757. A hunter taken from grass or in very low case should be treated as already fully detailed under condition. (6754.) Great care must be taken that all the alterations in heat of stable clothing, feeding, &c. are gradually brought about; by which means his flesh will harden gradually and by using free walking exercise, and increasing it as he advances in flesh and strength his wind also will become excellent.

6758. In the physicking of hunters, particularly when they are low in flesh, much caution is requisite that it be not over-done. It is the practice with some, and by no means a bad one, to give no physic, but to give more time in the preparation. Others, again give mild grass physic, which is an excellent plan, when the weather is fine. (See *Physicking*, 6544.)

6759. The preparation of a hunter in full flesh and not from grass depends principally on regular exercise, and the best hard food, physicking him or not, according as he may be suspected to be foul, or as a wind may seem to want mending, but above all, whatever is done, should be done regularly; and his exercise should be rather long continued than violent. Oats with beans are the proper hard food for hunters, taking care that the beans do not constipate the bowels, which must be obviated by bran mixed with the other food, if such should be the case. Bread is not necessary but for tender delicate horses but every thing should be of the best.

6760. The day before a horse is to hunt it is common to treat him somewhat differently but this is seldom necessary. It is evident he should be well fed, and that not late at night, that he may lie down early. Some feed in the morning which others avoid, but when it is considered as has been fully explained (6704) how ill a horse bears fasting, it will be at once seen that if very early in the morning, as by five o'clock, he could be fed with a moderate quantity of corn wetted, it would tend to support him through the day.

6761. On the return of a horse from hunting the care bestowed on him should be extreme; as on it depends the immediate recovery of his strength. If he have fasted very long and particularly if he be distressed to end of himself, horn down a pint of ale, with two pints of thick gruel. No prudent sportsman will bring in a horse hot, but if unavoidable accidents prevent this caution, let the horse be again led out for a few minutes, hooded and clothed, but he must have fresh clothes when afterwards dressed. Encourage him to stale as quickly as possible, after which proceed to hand-rub him all over carefully, place him before him a little of the best hay well sprinkled with water. If he refuse this, offer him three quarts of very clean chilled water. When perfectly dressed, let his feet be carefully examined, that stubs have not pierced them, or that his shoes have not been forced away by over-reaching, or by the action of clayey ground, or that thorns be not lodged in his knees, hocks, and sinews. After all these matters have been well attended to remove him from his stall to a loose box well bedded up. A loose box is all able to a hunter, it gives room for stirring to prevent the swelling of the legs, and is better than bandaging when it can be avoided, which gives a disinclination to lie down. If the horse be off his feed the next day, give him a cordial ball (see *Fox Phlegm*, 6565,) and a milk mash, and afterwards a few cut carrots, which will assist to bring him round more speedily.

### SUBJECT 3. *Working and Management of Riding Horses.*

6762. The working and managing of hackney or riding horses include what is required for them as pleasure horses for ordinary rings, and what they require when used for purposes of travelling or long journeys. It embraces also their stable management in general, with the proper care of horse and stable appointments, all which are usually entrusted to a servant, popularly called a groom, whose qualifications should be, moderate size, light weight, activity and courage, joined with extreme mildness and good temper, and above all, a natural love of horses, by which every thing required is done as a pleasure for the animal he loves, and not as a task for those he is indifferent to.

6763. The hackney for gentlemen's drives should be in high condition because a fine coat is usually thought requisite, and here the groom ought to be diligent that he may keep up this condition by regularly and dressing more than by heat, clothing and cordials. Whenever his master does not use the horse, he must not fail to exercise him (not principally by walking) to keep up his condition, and to keep down useless flesh and swellings of the heels. The horse appointments are to be peculiarly bright and clean. The bridle should be belleted and buckled that the bits may be removed to clean them without soiling the leather which cleaning ought not to be done with rough materials, but fine powder and polishing. On the return from exercise they should be wiped dry and then oiled. Two pair of girths should be used, that a clean pair may always be ready, and the same if saddle cloths are used.

6764. The preparation for, and the care of a horse on, a journey involve many particulars which should not escape the eye of the master. The first is, is the horse in hard travelling condition? Next, do his appointments all fit, and are they in proper order? The bridle for journeying should always be a double curved one. The snaffle can be ridden with certainly, but the master cannot do the work of the curb, in starting a horse, in saving him from the ground under stumbling or fatigue, or throwing him on his haunches, or in lightening his mouth. The bridle should not be new, but one to which the horse is accustomed. It is of still more consequence that the saddle be one that the horse has worn before, and that fits him thoroughly. The girths should also be of the best materials to prevent accidents; and if the saddle be liable to come forward, however objectionable the appearance a crupper had better be used. Some days before a long journey is attempted, if the shoe are not in order shoe the horse; but by no means let it be done as you set off, otherwise having proceeded on the journey a few miles, you find that one foot is pricked, and lameness ensues, or, if this be not the case one or more shoes pinch, or do not settle to the feet, all which cannot be so well altered as by your own smith.

6765. It is always best to begin a long journey by short stages, which accustoms the horse to continued exertion. This is the more particularly necessary if the horse has not been accustomed to travel thus, or if he be not in the best condition. The distance a horse can perform with ease depends greatly on circumstances.

Light coloured horses, very young ones, and such as are low in flesh, require often bathing, particularly in hot weather: horses in full condition, above their work, and well exercised, and such as are from seven to ten or twelve years old, are better when ridden a stage of fifteen or twenty miles, with a perpendicular length of bathing than afterwards, than when bated often, with short stoppages: the state of the weather should also be considered when it is very hot the stages should be necessarily shorter.

6736. To a proper consideration of the bathing times on a journey, the physiology of digestion should be studied. (6400.) Fatigue weakens the stomach, when we ourselves are tired, we seldom have much inclination to eat, and fatigue also prevents activity in the digestive powers. To allay these consequences, ride the horse only six or seven miles. If a handful of grain can be got at the road-side, it will wonderfully refresh your horse, and not delay you three minutes. In hot weather, let the horse have two or three godowns (gulps), but not more, of water occasionally as you pass a pond: this tends to prevent excessive fatigue. Occasionally walk yourself up-hill, which greatly relieves him, and at such time remove the saddle, by sitting which, only half an inch, you greatly relieve him: and during the time, perhaps, he may stale which also is very refreshing to him. It may be as well, in a stony country to take this opportunity of examining that no stones are got into the feet likewise.

6737. When a horse is brought into an inn from his journey: if he be very hot, first let him be allowed time to stale: let his saddle be taken off, and with a sweet knife draw the perspiration away: then, with a rag thrown over him, let him be led out and walked in some sheltered place till cool, by which means he will not afterwards break out into a secondary and useful sweat: but by no means let an idle rider leave him to dry without the stable. Being now dried, remove him to the stable, where let some good hay sprinkled with water be placed before him: if very thirsty give three or four quarts of water now, and the remainder in half an hour, and then let him be thoroughly dressed, hand rubbed, feet peeled, and foot-washed, but by no means let him be ridden into water: or if that practice is customary and cannot be avoided, let it be not higher than the knees, and afterwards insist on the legs being rubbed perfectly dry: but good hand rubbing and light spraying is better than washing. Having thus made him comfortable, proceed to feed him with corn and beans according as he is used.

6738. To feed a horse when very hard ridden, or if weakly and tender, it is often found useful to give bread, or bread & ale: if this be also refused, born down oatmeal and ale, or gruel and ale. It is of the utmost consequence if the journey is to be of several days' continuance, or if it is to consist of a great distance in one or two days, that the batings are sufficiently long to allow the horse to digest his food: digestion does not begin in less than an hour and is not completed in less than three: consequently any bait that is less than two hours fails of its object: and such a horse rather travels on his former strength than on his renewed strength, and therefore it cannot continue. After a horse is fed he will sometimes lie down: by all means encourage this, and if he is used to do it, get him a retired corner stall for the purpose.

6739. The right bathing of a journeying horse should embrace all the foregoing particulars with the addition of foot stopping, and care that his stable be of the usual temperature to that to which he is accustomed, and that no wind or rain can come to him. Give him now a full supply of water: if he has been at all exposed to cold, wash him, or if he has been dried by heat, do the same: otherwise, let a good proportion of oats and beans be his supper: with hay not to blow on half the night, but enough only to afford nutriment.

6740. When returned home from a journey: if it has been a severe one, let the horse have his fore shoes taken off, and, if possible, remove him to a loose box with plenty of litter: but if the stables be rough, or the pavement be uneven, put on tips, or merely loosen the nails of those shoes he has on: keep the feet continually moist by a wet cloth, and stop them at night if the shoes be left on: wash him regularly and if very much fatigued, or reduced let him have malt or carrots, and if possible, turn him out on turf or two in the middle of the day to graze: bleeding or phlebotomy are unnecessary unless the horse shows signs of fever: if the legs be inclined to swell, bath them with vinegar and chambrilys, and bandage them up during the day: but not at night, and the horse will soon recover to his former state.

#### SUMMARY 4. Horses in Carriages and Coaches.

6741. In working and managing horses in carriages: two wheeled chaises, and similar cases great feeling and nicety is required not to overload or overdrive the animal: so that the weight is duly proportioned between the wheels and horse's back, and that the harness does not pinch: but no directions on

this head can be of much use unless the driver be a humane and considerate person, and one who sets a just value on the services of the noble animal committed to him. In Russia, the drivers of two wheeled carriages, as droshkys, sledges, and others corresponding to our gigs and carriages, have a barbarous custom of teaching the horses to turn round their heads, the one to the left, and the other to the right (fig 850) the sight of which is very offensive to a stranger.

6742. In working and managing coach horses the same attention to grooming in all its departments is required as for saddle horses. Coach horses should never be brought into full work before they are five years old: when well fed on hard food, they may be worked at an average of thirty miles a day at twice. In general they should not be longer than five or six hours in the yoke at a time. Their principal meals should be in the morning and after their work is over for the day as the action of trotting fast materially impedes digestion.

#### SUMMARY 5. Working of Cart, Waggon, and Farm Horses.

6743. In working and managing cart and waggon horses a similar attention is requisite as for coach horses, though perhaps to a somewhat less degree, the animal being harder.

6744. The working and managing of farm horses includes the age at which they are put to work, the quantity of work they should perform, and their feeding and general management.

6745. The age at which horses are put to full work, in the labours of a farm, is usually when four or five years old, according to the nature of the soil, and the numbers of the team, but they are always understood to be able to pay for their maintenance after they are three years old by occasional work in ploughing and harrowing. Some think it probable they might be put to work at four years old, were the same attention paid to their breeding and rearing that is paid to cattle and sheep.

6746. The work which a farm horse ought to perform is evidently a question of circumstances, which does not admit of any precise solution: a two-horse plough may on an average, work about an English acre a day throughout the year: and, in general, according to the nature of the soil, and the labour that has been previously bestowed on it, a pair of horses, in ploughing, may travel daily from ten to fifteen.

sales, overcoming a degree of resistance equal to from four to ten hundred weight. On a well made road, the same horse will draw about a ton in a two-wheeled cart for twenty or twenty five miles every day, and one of the better sort, in the slow movement of the carrier or waggoner, commonly draws this weight by himself on the best turnpike roads. In some places horses are in the yoke, when the length of the day permits, nine hours, and in others ten hours a day, but for three or four months in winter, only from five to eight hours. In the summer season they are allowed to feed and rest two hours from mid-day, and in the latter they have a little corn on the field when working as long as there is day light, but none if they work only five or six hours (*Sup. Enc. Brit. art. Agr.*)

654. *The feeding of farm horses* is a subject of great agricultural importance, and has excited considerable discussion among speculative agriculturists, who have generally urged the great expenses attending it as an argument against horses in favour of oxen. Others, without preferring oxen to horses, have, instead of corn and hay proposed to feed them on roots, leaves, wheats, and even haws from the hedges. The latter have been given in large quantities by West of Hampshire, and it is said (*Complete Farmer art. Trees*) were found to answer. That horses as well as men may live on very inferior food is evident, but that either will be able to perform their work under such treatment, as well as if they were properly nourished, is contrary to reason and experience. It is observed by the judicious writer so often quoted, that horses can never perform their labour according to the present course of husbandry on carrots, turnips, potatoes or other roots, alone, or as their chief food. They will work and thrive on such food but they will work as much more, and thrive as much better with oats or beans in addition, as fully to repay the difference in expense. One of the three meals a day which farm horses usually receive, may consist of roots and a few of them every twenty four hours, are highly conducive to the health of the animals, but we have never had occasion to see any horse work regularly throughout the year, in the way they are usually worked in the best cultivated districts, without an allowance of at least an English peck of oats, or mixed oats and beans, daily less or more at particular periods, but rather more than this quantity for at least nine months in the year.

655. *Grass* does not consist of giving much grain to young horses, thinking it expensive, and not so conducive to their health as when they are supported on green food. In the winter and spring months, a few turnips are eminently beneficial to young horses, by keeping their blood in good order, swelling their bone, and hastening their growth. A plentiful supply of grass in summer ought always to be allowed, as their condition through the winter depends greatly upon that circumstance. It is an object deserving of attention, that flesh once gained ought never to be lost, but that every animal whatever should be kept in a progressive state of improvement, and not suffered to take a retrograde course, which afterwards must be made up by extra feeding, or a loss be sustained, in a direct proportion to the degree of retrogradation that has actually occurred.

656. *The leanness of a farmer's working cattle* and their reluctant movements clearly mark his unprosperous condition. These are particularly evident in such as turnip-growing feeding, ploughing, harrow-work, &c. which require to be executed with so great despatch in our variable climate, that unusual exertions are often indispensable. At these times it is hardly possible by the richest food and the most careful treatment to prevent the animals from losing flesh sometimes even when their spirit and vigour are not perceptibly impaired. Such labours I never do not continue long, and should always be followed by a corresponding period of indulgence. It is particularly dangerous and unprofitable to begin the spring labour with horses worn down by bad treatment during winter. (*Sup. Enc. Brit. art. Agr.*)

657. *Donaldson* observes, that the coarse garbage with which farm horses are commonly stuffed, profitably or otherwise, is the real cause of the frequent occurrence among them of blindness, greases, and colic more particularly the last, which with care might be prevented from happening so frequently. The remedy lies in physic, once or twice a year either the regular aloetic dose, or salts given in pale of warm water, or sulphur and cream of tartar, one third of the latter mixed in the corn. All horses kept in the stable become more or less internally loaded, and it is an error to suppose cart-horses are not equally benefited with others by purging physic.

658. *The cleaning and dressing of farm horses* was formerly very little attended to, but at present its importance to the health of the animal is better understood. Donaldson recommends that the heels, legs, bend of the knee, and hock, the twelfth under the flank, in short, all parts out of sight, of cart horses, whilst standing in the house, should be kept perfectly free from dirt and scurf, and the skin supple the parts more in sight will take care of themselves. In a deep country it is much the better practice, notwithstanding the prejudice to the contrary to trim their legs coach horse fashion. It is now well understood, the editor of *The Farmer's Magazine* observes, that the liberal use of the brush and the currycomb twice a day, frequent but moderate meals, consisting of a due proportion of succulent joined to more solid food, abundance of fresh litter and great attention to method and cleanliness, are as indispensable in the stable of a farmer as far as is consistent with a just regard to economy, as they have always been held to be in the treatment of horses kept for pleasure. Good dressing with all well informed and attentive men is considered to be no less necessary to the thriving of the horse than good feeding according to a common expression it is equal to half the food.

659. *The general management of farm horses in the improved districts of the north* may be presented as a good example. There for about four months in summer horses are fed on pastures or on clover and rye-grass, and taken out green and brought home to the stable or fold yard the latter method being by far the most economical and advantageous. For the other eight months they are kept on the straw of oats, beans, and peas, and on clover and rye grass hay. As soon as the grass fails towards the end of autumn, they have hay for a few weeks, and when the days become so short as to allow of no more than from six to eight hours work they are very generally fed with different kind of straw according to the circumstances of the farm, in the month of March they are again put to hay till the grass is ready for being cut. Throughout all the year they are allowed more or less corn, when constantly worked and during the time they are on dry fodder particularly when on straw they have potatoes, yams, or Swedish turnips, once a day sometimes boiled barley, and in a few instances carrots. A portion of some of these roots is of great importance to the health of horses, when succulent herbage is first exchanged for hay at the end of autumn, and it is no less so towards the latter end of spring when hay has become spleen, and the labour is usually severe. At these two periods therefore it is the practice of all careful managers to give an ample allowance of some of these roots, even though they should be withheld for a few weeks during the intermediate period.

660. *The quantity of these different articles of food* must depend on the size of the horse, and the labour they perform, and the value upon the prices of different seasons, and, in every season, on the situation of the farm with respect to markets, particularly for hay and roots which bring a very different price near large towns, and at a few miles distant. It is for these reasons that the yearly expense of a horse's maintenance has been estimated at almost every season from 12s. to 40s. But it is only necessary to attend to the expense of feeding horses that are capable of performing the labour required of them, under the most correct and spirited management. Such horses are fed with oats, sometimes with beans, three times a day, for about eight months, and twice a day for the other four, when at grass and at the rate of eight fods per bushel, each horse will eat fifteen quarters of oats, or twenty bushels Lanthorn measure in the year. When on hay he will require about one stone of twenty two pounds *averdupois* daily and five pounds more if he does not get roots. One English acre of clover and rye-grass, and tares, may be necessary for four months soiling, and a quarter of an acre of potatoes, yams, or Swedish turnips, during the eight months he is fed with hay or straw. The use of these roots may admit of a small diminution of the quantity of corn in the winter months, or a part of it may be, as it almost always is, of an inferior quality.

6794. The expense of feeding a horse throughout the year may therefore be estimated, in regard to grain, as follows:—

Grain, fifteen quarters.  
Hay, one acre of clover and ten acres of turnips.  
Six pence of oats and November: March, April, and May, 1s. 10d.

Stable for other four months, half the value of hay.  
Furniture, yards, or Swedish turnips, 2 acres.  
(See also p. 497.)

6795. The extent of land required for a horse's maintenance, supposing the soil to be of a medium quality may be about five acres; that is, for oats three acres, mowing one, and one more for hay and roots. (In such soils four acres will be sufficient; but on poor soils, and wherever horses are kept as pasture, the possession of six acres and a half, or seven acres, will be consumed by one of them, when worked in the manner already mentioned. The straw of about two acres must be allowed for fodder and litter the last of which has not been stated above.) Because, at a distance from towns, what is allowed for litter must, at any rate, be converted into dung. If sixty acres, therefore, should be assumed as the average extent of land that may be kept in cultivation by two horses, according to the best courses of modern husbandry the produce of ten acres of this will be required for their maintenance; or, a horse consumes the produce of one acre out of every six which he cultivates, according to a four or six years course, and something more than one acre out of every five which he ploughs annually. (General Report of Scotland, vol. III. p. 192.)

## CHAP. II

The Ass.—*Equus Asinus* L. *Ass*, Fr. *Esel*, Ger. *Asno*, Span. and *Anno*, Ital.

6796. The ass is a native of the mountainous deserts of Tartary of Arabia, Persia, and other parts of the Asiatic continent and at present is very generally domesticated throughout most civilized countries. The wild ass feeds chiefly on the most saline or bitter plants of the desert, as the kaks, stripices, chenopodium, &c. and also prefers the saltest and most brackish water to that which is fresh. Of this the hunters are aware and usually station themselves near the ponds to which they resort to drink. Their manners greatly resemble those of the wild horse. They assemble in troops under the conduct of a leader or sentinel and are extremely shy and vigilant. They will, however stop in the midst of their course, and even suffer the approach of man, and then dart off with the utmost rapidity. They have been at all times celebrated for their swiftness. Their voice resembles that of the common ass, but is shriller.

6797. The excellencies and defects of the common ass have simply engaged the lively pens of several descriptive writers on the history of animals and of none with more happy effect than those of the eloquent Buffon, and the ingenious Abbi Le Rouge. The ass, in his natural temper is humble, patient, and quiet, and bears correction with firmness. He is extremely hardy both with regard to the quantity and quality of his food, contenting himself with the most harsh and disagreeable herbs, which other animals will scarcely touch. In the choice of water he is, however very nice drinking only of that which is perfectly clear, and at brooks with which he is acquainted. He is very servicable to many persons who are not able to buy or keep horses; especially where they live near deserts or commons, the labour of which will keep him; being contented with any kind of coarse herbage, such as dry leaves, stubble, thistles, brambles, &c. and any sort of straw. He requires very little looking after and sustains labour beyond most others. He is seldom or never sick

and endures hunger and thirst longer than most other kinds of animals. The ass may be made use of in husbandry to plough light lands, to carry burdens, to draw in mills, to fetch water out of wells, or any other similar purposes. The female (see 681.) is also useful in many cases for her milk, which is excellent; and she might be of more advantage to the farmer if used, as in foreign countries, for the breeding of mules. The skin of the ass is extremely hard and very elastic, and is used for various purposes such as to cover drums, make shoes, or parchment. It is of the skin of this animal that the Orientals make the sagri, or, as we call it, shagreen. The milk of the ass is the lightest of all milks, and is recommended by medical men

to persons of delicate constitutions; the flesh, and the hair of the tail and mane are used as those of the horse.

6798. The ass attains his full growth in three or four years and may then be put to work. Like the horse, he will live to 25 or 30 years: it is said the female lives longer than the male but, perhaps, this happens from their being often pregnant, and at those times having some care taken of them, instead of which the males are constantly worn out with fatigue and labour. They sleep less than the horse, and do not lie down to sleep, except when they are exceedingly tired. The male ass also lasts much longer than the female; the older he is, the more ardent he appears; and, in general, the health of this animal is much better than that of the horse; he is less delicate, and not nearly so subject to maladies. Ophthalmia, which may be reckoned among the indigenous of the cultivated horse, is almost unknown to the ass. Consumption of the feet also is very seldom observed in him.

6799. The different breeds or races of the ass are much less known than those of the horse because in this country they have not been taken the same care of or followed with the same attention. Travelers inform us that there are two sorts of asses in Persia; one of which, being slow and heavy is used for burdens; and the other is kept like horses for the saddle. The latter have smooth hair, carry the head well, and are much quicker in their motion; but when they ride them they sit nearer the buttocks than when on horseback. They are dressed like horses, and like these are taught to amble; and they cleave their nostrils to give them more room for breathing. According to Dr. Russell, there are two sorts in Syria, one of which is the same, and the other very large, with remarkably long ears; but both kinds are employed for the purpose of carrying burdens and sedan chairs. (See 682.)

6764. *In breeding from the ass, the same general rules should be attended to as in the horse breeding. The male ass will procreate at the age of two and a half years, and the female still earlier. The stallion ass should be chosen from the largest and strongest of his species; he must at least be three years old, but should not exceed ten; his legs should be long, his body plump, head long and light, eyes brisk, nostrils and chest large, neck long, loins fleshy ribs broad, rump flat, tail short, hair shining, soft to the touch and of a deep grey. These are reckoned the best shaped that are well squared have large eyes, wide nostrils, long necks, broad breasts, high shoulders, a great back short tail, the hair sleek, and of a blackish colour.*

6765. *The best time for covering is from the latter end of May to the beginning of June, nor must the female be hard worked whilst with foal, for fear of casting; but the more she is worked, in moderation the better he will thrive. She brings forth her foal in about a twelvemonth, but, to preserve a good breed, she should not produce more than one in two years. She should be covered between the months of March and June. The best age to breed at is from three years old to ten. When the foal is cast, it is proper to let it run a year with the dam, and then wean it by tying up and giving it grass, and sometimes milk; and when it has forgot the teat, it should be turned out into a pasture; but if it be in winter it must then be fed at times, till it be able to shift for itself.*

6766. *The ass may be broken and trained at the end of the second year, but should not be worked sooner than the third year. Breaking is easily effected when two years old or it may be let alone still longer as till three years. It is easily done by laying small weights on his back, and increasing them by degrees; then set a boy upon him, and so increase the weights as may be proper till they are sufficiently heavy.*

6767. *The age of the ass is known by his teeth in the same manner as the horse. At two years and a half old the first middle incisor teeth fall out, and the other on each side soon follow; they are renewed at the same time, and in the same order.*

6768. *The anatomy and physiology of the ass do not differ from those of the horse essentially. The cartilages of the ears are, however, considerably more elongated the spinous processes of the dorsal vertebrae forming the withers are less extensive; and the bones of the extremities in general are less angularly placed, from whence results his inferiority in speed. It is also to the unbounding lines of the spine, that his suddenness is rendered so uneasy to the rider on the middle of his back. Some species occurs in the feet, which like the horses of arid climates, are small and upright. His laryngeal sonorous sacs and cordæ vocales are not altogether like those of the horse from whence his aptitude to bray instead of neighing. In the ass there are three laryngeal sacs as in the horse, but instead of a wide opening into them, there is a small round hole, and the interior sac is a real bag of considerable size. In the horse there is also, at the commencement of the cordæ vocales, a slight membranous fold not visible in the ass. These organs in the mule are compounded of these forms. Braying appears produced through the mouth, whereas neighing is principally effected by the nose. There is a hollow membranous cavity at the back of the mouth that is greatly assistant to this trumpet-like noise which is effected by convulsively displacing the velum palati by alternate inspirations and expirations.*

6769. *The diseases of the ass as far as they are known bear a general resemblance to those of the horse. As he is more exposed however and left to live in a state more approaching to natural, he has few diseases. These few, however are less attended to than they ought to be and it is for the veterinary practitioner to extend to this useful and patient animal the benefit of his art, in common with those of other animals. The ass is seldom or never troubled with vermin probably from the hardness of its skin.*

6770. *The ass is shod with a narrow web, and with heels projecting beyond the heel of the foot, and slightly turned up, for he seldom overreaches, but much care is required in using small nails and in very carefully driving them. The hinder shoes differ little from those used for the fore feet.*

### CHAT III

#### *The Mule and Hinny Hybrids of the Horse and Ass.*

6767. *The mule (Equus Asinus var γ Mulus L. Grand Mulet Fr Grosseau Mulet, Ger Mulo, Span and Ital.) is the hybrid produce of an ass with a mare having a large clumsy head, long erect ears, a short mane and a thin tail.*

6768. *The hinny (Equus Asinus, var δ Hinnyus L. Bardeau or Petit Mulet, Fr, Kletter Mulet, Ger Mulo, Span and Ital.) is the hybrid produce between the ass and a stallion the head is long and thin, the ears are like those of a horse, the mane is short, and the tail is well filled with hair. The hinny is much less common than the mule, because, being less hardy and useful than the other, he is never cultivated.*

6769. *The mule commonly so called, is much valued for the saddle, and for drawing carriages in Spain, Portugal, Italy and the East and in the warmer parts of America. In those countries where great attention is paid to the breed, it is as tall as the horse, exceedingly well limbed, but not so handsome, especially about the head and tail. These animals are mostly sterile some, indeed, have thought that they are altogether incapable of producing their kind but some few instances have occurred in which female mules have had foals, and in which even the male has impregnated females both of the ass and horse species, though such instances are exceedingly rare.*

6770. *The mules made use of in the southern parts of Europe are now brought to an astonishing perfection as well as great size. (fig 853.) They are usually black strong, well limbed, and large, being mostly bred out of fine Spanish mares. They are sometimes fifteen or sixteen hands high, and the best of them worth forty or fifty pounds. No creature is so proper for large burdens, and none so sure-footed. They are much stronger for draught than our horses, and are often as thickset as our day horses, and will travel several months together with six or eight hundred weight upon their backs. Some think it surprising that these animals are not more propagated here, as they are so much harder and stronger than horses, less subject to diseases, and capable of living and working to twice the age of a horse. Those that are bred in cold countries are more hardy and fit for labour than those bred in hot; and those which are light made are fitter for riding than horses, as to the walk and trot but they are apt to gallop rough; though these do it much less than the short-made ones. The general complaint made against them is, that they kick and are stubborn; but this is owing to neglect in breeding them, for they are as gentle as horses in countries where they are bred with proper care.*

6771. *In the breeding of mule mares that are of a very large breed and well made should be employed. They should be young, full of life, large berrilled, but small limbed, with a moderate-sized head, and a good forehead. It is found of advantage to have the foals from the time of their being dropped often*

handled, to make them gentle. It prevents their hurting themselves by shuddering and sudden frights, and they are much easier broken at the proper age, and become docile and harmless, having nothing of that viciousness which is so commonly complained of in these animals. They may be broken at three years old, but should never be permitted to do much hard work till four as they are thus secured from being hurt by hard labour till they have acquired strength enough to bear it without injury. An expert breeder of these animals found, that feeding them too well while young, was not only incurring a much larger expense than was any way necessary, but also made them wonderfully nice and delicate in their appetites ever after. He therefore contented himself with giving them food enough to prevent their losing flesh, and to keep up their growth without palling their

appetites with delicacy, or making them over fat. He also took care to defend them from the injuries of the weather by allowing them stable room, and good litter to sleep on, besides causing them every day to be well rubbed down with a hard whip of straw by an active groom. This was scarcely ever omitted, particularly in cold, raw wet weather when they were least inclined to exercise themselves. When three years old, mules are proper for use.

6772. The shoe for the mule is by some made not unlike the bar shoe before, and the common shoe behind. By some both fore and hind shoes are made to project considerably beyond the toe under an idea of increasing the points of contact with the ground. but the most usual shoe is one formed between the usual horse and ass shoe.

#### CHAP. IV

*Neat or Horned Cattle* — *Bœs* L. *Mammalia Pécora* L. and *Ruminacea* Cuv. *Bœs a cornu*, Fr. *Vieh*, Ger. *Canado*, Span. and *Bastuno*, Ital.

6773. The neat or horned cattle used in agriculture are included under two species of *Bœs* the *B. Taurus* or ox and the *B. bubalus* or buffalo the latter less used in Britain than on the Continent and in other countries. These animals are more universally used as beasts of draught and burden than the horse and have the additional advantage of furnishing excellent food and other valuable products. There is scarcely a country in which the ox or the buffalo is not either indigenous, or naturalised and cultivated, while in many parts of the world the horse is either wanting, or reserved for the purposes of war or the saddle.

*BOES* L. The Ox. — *Bœs Taurus* L. *Ochs*, Ger. *Bœuf* Fr. *Buey* Span., and *Bue*, Ital.

6774. The male ox is the bull (*Taurus*, Fr. *Stier* Ger. *Toro*, Span and Ital.) and the female the cow (*Vache* Fr. *Kuh*, Ger. and *Vaca*, Span. and Ital.) The bull and cow inhabit various parts of the world, and, as already observed, are domesticated every where. In most countries, however they are the mere creatures of soil and climate, the same attention in breeding and rearing that is bestowed on the horse being withheld. The natural habits little restrained or the form little improved for the purposes of milking, fattening, or for labour. It is almost exclusively in Britain that this race of animals has been ameliorated so as to present breeds for each of these purposes, far superior to what are to be found in any other country. Notwithstanding this, however, much certainly remains to be known regarding the nutriment afforded by different kinds of herbage and roots, the quantity of food consumed by different breeds, in proportion as well to their weight at the time, as to the ratio of their increase and the propriety of employing large or small animals in any given circumstances. Even with regard to the degrees of improvement made by fattening cattle generally, from the consumption of a given weight of roots or herbage, so great accuracy is commonly attempted. machines for weighing the cattle themselves and their food, from time to time, not being yet in general use in any part of Britain. We shall consider this valuable family as to variety, criteria, breeding, saving, feeding, working, fattening, and milking. the manufacture of milk will be treated of in a succeeding chapter.

#### SUBJECT 1. Varieties and Breeds of the Bull.

6775. The varieties of the wild ox are the *houassu* and the *Meon* (fig. 112); the first with a long mane, and the last with a grizzled back. They inhabit the woods in Madagascar and many other countries of the East; and the Meon is even said to be found in Poland.

5776. The varieties of the European cow, according to Akten, are innumerable. The pliancy of their nature is such that they have been tamed into many diversities of shape, and various qualities have been given them very different from the original stock. The wis or cows of Lithuania, are almost as large as the elephant while some of those on the Urampian hills are little above the size of a goat; and cows are found of every diversity of size between the one and the other. They are not less varied in their shapes. The *slon*, which is a species of the cow family and which readily propagates with our cows, wears a strong shaggy mane, like the lion's head, like the goat as much hair under its neck and breast as covers its fore legs; a hump upon its shoulders, nearly as large as that worn by the camel (sometimes forty or fifty pounds in weight) with a tail that scarcely reaches the top of its buttock and it resembles the lion much more than it does our domesticated cows, or other varieties of its own species. (African.)

5777. The diversity of qualities in the cow family is also very great. Our cows are so groling and inacti e, that they scarcely know the road from their stall to their pasture, while those of the Hottentots are so tractable as to be intrusted with the charge of other animals, and keep them from trespassing on the fields of grain or other forbidden ground. They also fight their master's battles, and pore his enemies with their horns. Our dairy cows are so feeble and inactive, that they are hurt by travelling twice a day some slowly, one mile from the byre to their pasture; while those of Tartary are used as riding animals, and in drawing carriages. Those of Hindostan draw the coaches, and maintain their race with horses at the full trot; and the Hottentots teach their cows to hunt down the elk antelope. Cows of the wild neglected breed can with difficulty be removed from one enclosure or one hill to another while those on whom due attention has been bestowed are docile, and submit to perform all sorts of labour. Some cows will yield upwards of twenty Scots pints of milk per day while others will not give so much in ten, perhaps not in twenty days. These are not so many different species of animals, but all of them one and the same species, all capable of generating with each other a perfect offspring. All these varieties have been formed from the parent stock partly by the diversity of soil and climate, or other accidental or adventitious circumstances, and partly of late by human skill and industry. (Dairy Husbandry p. 17.)

5778. The varieties of the cultivated cow are the European, Indian, Zebu, Guernsey, Ayrshire, Madagascary, Thibian and African. From the European variety have been formed the different breeds cultivated in Britain. They are very numerous, but we shall only notice such as are in most esteem. These different breeds are generally distinguished by the length or flexure of their horns by the absence of horns; by the district where they are supposed to have originated or in which they abound, or exist in the greatest purity or by the name of the breeder.

5779. The long-horned or Lancashire breed of cattle (fig. 854) is distinguished from others by the length of their horns, the thickness and firm texture of their hides, the length and closeness of their hair, the large size of their hoofs and their coarse, leathery thick necks. They are likewise deeper in their fore quarters, and lighter in their hind quarters, than most other breeds; narrower in their shape, less in point of weight than the short horns, though better weighed in proportion to their size and though they give considerable less milk, it is said to afford more cream in proportion to its quantity. They are more varied in their colour than any of the other breeds, but, whatever the colour be, they have in general a white streak along their back, which the breeders term *finched* and mostly a white spot on the inside of the hough. (Cattle p. 55.) In a general view this race, notwithstanding the singular efforts that have been made towards its improvement, remains with little alteration for except in Leicestershire none of the subvarieties (which differ a little in almost every one of those counties where the long horns prevail) have undergone any radical change or any obvious improvement. The improved breed of Leicestershire (fig. 855) is said to have been formed by Webster, of Cauley near Coventry in Warwickshire, by means of six cows brought from the banks of the Trent, about the beginning of the present century, which were crossed with bulls from Westmoreland and Lancashire. Bakewell of Dishley in Leicestershire, afterwards got the lead as a breeder by selecting from the Cauley stock and the stocks of several other eminent breeders have been traced to the same source. (Marschall's Midland Counties vol. i. p. 518.)

5780. The short-horned, sometimes called the Dutch breed (fig. 856), is known by a variety of names, taken from the districts where they form the principal cattle stock or where most attention has been paid to their improvement: thus, different families of this race are distinguished by the names of the *Holderness*, the *Yarwater*, the *Yorkshire*, *Darhams*, *Northumberland*, and other breeds.

The *Yarwater* breed, a variety of short horns, established on the banks of the *Yar*, at the head of the vale of York, is at present in the highest estimation, and is alleged to be the true Yorkshire short-horned breed. Bulls and cows from this stock, purchased at most extraordinary prices are spread over all the north of England, and the border counties of Scotland. The horns, head, and neck of these cattle are fine; the hide is very thin; the skins full; the lean broad; the carcass throughout large and well fashioned; and the flesh and fatting quality equal, or perhaps superior, to those of any other large breed. The short-horns give a greater quantity of milk than any other cattle; a cow usually yielding twenty-four quarts of milk per day making three firkins of butter during the grass season; their colours are much varied, but they are generally red and white mixed, or what the breeders call *speckled*. The heaviest and largest span of the short-horned breed when properly fed victual the East India ships, as they produce the thickest beef, which,

red and white mixed, or what the breeders call *speckled*. The heaviest and largest span of the short-horned breed when properly fed victual the East India ships, as they produce the thickest beef, which,

by retaining its joints, is the best adapted for such long voyages. Our royal navy should also be victualled with these beef, from the joints made by contractors, and from other sources, it is feared our horses have not been fed with food of an inferior quality; however, the coal ships from Newcastle, Shields, Sunderland, &c., are wholly supplied with the beef of these valuable animals. These oxen commonly weigh from 80 to 100 stone (16 lbs. to the stone), and they have several times been fed to 180, 190, and some particular ones to upwards of 120 stone, the fore-quarters only (Culley, p. 44.)

6761. In comparing the breeds of long and short-horned cattle, Culley observes that the long-horns excel in the thickness and firm texture of the hide, in the length and closeness of the hair, in their beef being finer grained, and more mixed and marbled than that of the short-horns, in weighing more in proportion to their size, and in giving richer milk, but they are inferior to the short-horns, in giving a less quantity of milk, in weighing less upon the whole, in affording less tallow when killed, in being generally slower feeders, and in being coarser made and more saucy or bullish in the under side of the neck. In few words, says he, the long-horns excel in the hide, hair and quality of the beef, the short-horns in the quantity of beef, tallow and milk. Each breed has long had, and probably may have, its particular advocates; but if he may hazard a conjecture, is it not probable that both kinds may have their particular advantages in different situations? Why not the thick firm hides, and long close-set hair, of the one kind, be a protection and security against those impetuous winds and heavy rains to which the west coast of this island is so subject, while the more regular seasons and mild climate upon the east coast are more suitable to the constitutions of the short-horns.

6762. The middle-horned breeds comprehended, in like manner several local varieties, of which the most noted are the *Devons*, the *Sussex*, and the *Herefords* the last two, according to Culley being varieties of the first, though of a greater size, the Herefords being the largest. These cattle are the most esteemed of all our breeds for the draught, on account of their activity and hardiness they do not milk so well as the short-horns, but are not deficient in the valuable property of feeding as an early age, when not employed in labour.

6763. The *Devonshire cattle* (fig. 857) are of a high red colour (if any white spots they reckon the breed impure, particularly if these spots run one into another), with a light-dun ring round the eye, and the muzzle of the same colour fine in the bone, clean in the neck, horns of a medium length bent upwards, thin faced, and fine in the chops, wide in the hips, a tolerable barrel, but rather flat on the sides, tail small, and set on very high they are thus skinned, and silky in handling, fed at an early age or arrive at maturity sooner than most other breeds, (Culley p. 51.) Another author observes, that they are a model for all persons who breed oxen for the yoke. (*Perfection of Livestock* vol. i. p. 112.) The weight of the cows is usually from 50 to 60 stone, and of the oxen from 60 to 80 the North Devon variety in particular from the fineness in the grain of the meat, is held in high estimation in South-  
field. (*Duckworth's Practical Agriculture*, vol. ii. p. 150.)

6764. *Lewes* says that the race of red cattle of North Devon and Somerset is doubtless one of our original breeds, and one of those which have preserved most of their primitive form the excellence of this form for labour is best proved by the fact, that the fashionable substitution of horses has made no progress in the district of these cattle, by their high repute as feeders, and for the superior excellence of their beef, which has been acknowledged for ages. They are, he says, the speediest working-oxen in England, and will trot well in harness in point of strength they stand in the fourth or fifth class. They have a greater resemblance to deer than any other breed of best cattle. They are rather wide than middle-horned, as they are sometimes called some, however have regular middle-horns, that is, neither short nor long, turned upward and backward at the points. As milkers, they are so far inferior to both the long and short horns, both in quantity and quality of milk that they are certainly no objects for the regular dairy, however pleasing and convenient they may be in the private family way.

6765. The *Sussex and Herefordshire cattle* (fig. 858) are of a deep red colour, with fine hair and very thin hides, neck and head clean, the face usually white horns neither long nor short, rather turning up at the points in general, they are well made in the hind quarters, wide across the hips, rump, and arken but narrow in the chine tolerably straight along the back, ribs too flat, thin in the thigh, and bone not large. An ox six years old, will weigh when fat, from 80 to 100 stone the fore-quarters generally the heaviest. The oxen are mostly worked from three to six years old, sometimes till seven, when they are turned off for feeding. The Hereford cattle are next in size to the Yorkshire short-horns both size and the Gloucester variety are highly eligible as dairy stock, and the

females of the Herefords have been found to fatten better at three years old than any other kind of cattle except the greyed heifers of Warwick. (*Marshall's Economy of Gloucestershire*.)

6766. The *polled or hornless breeds*. The most numerous and esteemed variety is the Galloway breed (fig. 859) so called from the province of that name, in the south-west of Scotland, where they most abound. The true Galloway bullock "is straight and broad on the back, and nearly level from the level to the rump, broad at the loins, not, however with hooked bones, or projecting knots, so that when viewed from above, the whole body appears beautifully rounded; he is long in the quarters, but not broad in the twist he is deep in the chest, short in the leg, and moderately fine in the bone, clean in the chop and in the neck, his head is of a moderate size, with large rough ears, and full but not prominent eyes, or heavy eyebrows, so that he has a calm though determined look, his well proportioned form is clothed with a loose and mellow skin, adorned with long soft glossy hair" (*Galloway Report*, p. 284.) The prevailing colour is black or dark bay, and, though they are occasionally found of every colour, the dark colours are uniformly preferred.

The Galloways are rather undressed, not very different from the size of the Devons, but so much less than the long-horns, as the long-horns are less than the short-horns. On the best farms,

857

the average weight of bullocks three years and a half old, when the greater part of them are driven to the south, has been stated at about 60 stone, average; and some of them, shipped in England, have been brought to nearly 100 stone.

6787. *The general properties of this breed* are well known in almost every part of England, as well as in Scotland. They are sometimes sent from their native pastures directly to Smithfield a distance of four hundred miles, and sold at once to the butcher; and in spring they are often shown in Norfolk, immediately after their arrival, in as good condition as, or even better than, when they begin their journey; with full feeding there is perhaps no breed that sooner attains maturity and their flesh is of the finest quality. Culley was misinformed about the quantity of milk they yield which, though rich is by no means abundant. It is alleged not to be more than seventy or eighty years since the Galloways were all horned, and very much the same in external appearance and character with the breed of black cattle which prevailed over the west of Scotland at that period and which still abounds in perfection, the largest-sized ones in Argyshire, and the smaller in the Isle of Skye. The Galloway cattle at the time alluded to were coupled with some hornless bulls, of a sort which do not seem now to be accurately known, but which were then brought from Cumberland, the effects of which crossing were thought to be the general loss of horns in the former, and the enlargement of their size. The continuance of a hornless sort being kept up by selecting only such for breeding, or perhaps by other means, as by the practice of eradication with the knife the horns in their very young state. (*Coventry on Live Stock* p. 82.)

6788. *The Suffolk downs*, according to Culley are nothing more than a variety of the Galloway breed. He supposes them to have originated in the intercourse that has long subsisted between the Scotch drovers of Galloway cattle, and the Suffolk and Norfolk graziers who feed them. The Suffolks are chiefly light downs, thus differing from the Galloways and are considered a very useful kind of little cattle, particularly for the dairy. (*Culley* p. 63. *Parkinson*, vol. 1 p. 114.)
